Abstract

In collaborative tasks with asymmetric information, participants coordinate their understanding through interaction. We ask whether gaze provides evidence about grounding across two such tasks. Working from discrete behavioral annotations, we map HCRC MapTask (Anderson et al., 1991) and MUNDEX (Türk et al., 2023) into a shared partner/task/away vocabulary and compute gaze features around task-relevant dialogue units. In both corpora, aligned reference interpretations (MapTask) and UND (understood) judgments (MUNDEX) are associated with more task-directed gaze and with less partner-directed gaze, lower gaze entropy, and fewer gaze transitions. The associations are clearest for the participant leading the task: in giver-produced references, and in explainer judgments, which also co-vary with the explainee’s gaze. In same-speaker MapTask reference chains, the speaker’s gaze entropy is lower at the mention where a previously non-aligned referent becomes aligned. The best gaze feature groups improve modestly over controls under grouped cross-validation: temporal features in MapTask and raw proportions in MUNDEX. Because effects are small and several weaken when recurring participants rather than dialogues are the unit of inference, we treat gaze as one contributing cue to grounding, to be interpreted alongside task and dialogue context.

1 Introduction

In collaborative tasks where participants hold different private information, mutual understanding cannot be assumed from shared context alone. It must be built and tracked through interaction (Clark and Wilkes-Gibbs, 1986; Clark and Brennan, 1991). Gaze is an observable cue to this process: participants look at task materials, at each other, or away while giving instructions, checking understanding, and coordinating their perspectives. Some corpora annotate gaze from video as discrete categories of

where participants look, rather than as eye-tracking coordinates. These annotations can be used to study the relationship between gaze and grounding, but they are often corpus-specific, making it difficult to compare across tasks.

We study two settings where information asymmetry forces participants to continuously coordinate understanding. In HCRC MapTask (Anderson et al., 1991), a giver and a follower navigate with maps that differ in their landmarks; perspectivist grounding labels record each participant’s interpretation separately (Li et al., 2026a). In MUNDEX (Türk et al., 2023), an explainer teaches a board game to an explainee; both annotate the explainee’s moment-by-moment understanding retrospectively.

Building on within-corpus studies, we compare grounding-related gaze patterns across tasks. We contribute (1) a shared partner/task/away representation that maps two gaze ontologies and applies to other corpora with video-coded gaze annotations; (2) evidence of directional convergence across distinct grounding measures, clearest for the participant leading the task; and (3) a within-speaker reference-chain analysis showing that speaker gaze entropy is lower when a referent becomes aligned. Grouped prediction and role-stratified tests characterize the strength and scope of these associations.

2 Related Work

Grounding theory holds that interlocutors seek and provide evidence of understanding as a conversation progresses (Clark and Wilkes-Gibbs, 1986; Clark and Brennan, 1991). Visual evidence is part of this process: when directors could see builders’ workspace in a Lego assembly task, builders displayed understanding through actions, gaze, and head gestures, and directors adjusted their utterances accordingly (Clark and Krych, 2004). Gaze also carries referential information, as matchers

Figure 1: MapTask dialogue q8ec4 with gaze mapped to the shared partner/task/away vocabulary. Each horizontal bar is a gaze event; dashed vertical lines mark two reference expressions for the same landmark. The follower's reference to *a disused monastery* is *pending* (red dashed line): the follower repeatedly glances at the partner (orange bars). After the giver's re-mention, the reference is *aligned* (green dashed line). Both participants' gaze remains predominantly task-directed (blue bars).

used a director's gaze to identify targets before the linguistic point of disambiguation (Hanna and Brennan, 2007).

Map-based tasks tie gaze more directly to grounding complexity. In MapTask dialogues with visibility, followers looked up at givers more often while discussing landmarks that differed between their maps (Boyle et al., 1994). In a direction-giving study, Nakano et al. (2003) coded gaze at the partner, the map, and elsewhere, and found that nonverbal patterns differed by dialogue act: after a giver's assertion, a listener's sustained gaze at the speaker was usually followed by elaboration, whereas continued attention to the map more often preceded the next instruction. Murat and Vogel (2026) aligned both participants' MapTask gaze with turn boundaries and related it to dialogue acts, lexical entropy, and repetition; partner-directed gaze at turn ends accompanied turns expressing difficulty, while map-directed gaze was more typical of exchanges without obstacles or disagreement.

In MUNDEX, understanding was annotated through retrospective video recall (Türk et al., 2023). Wang et al. (2026) related explainees' self-reported understanding to speaker information value, syntactic complexity, and listener gaze entropy, computed as the average negative log-probability of automatically estimated gaze labels under a sequence model; adding these cues to textual features improved classification. Lazarov and Grimmer (2026) manually coded MUNDEX gaze as directed to the partner, the table, or away; in the explanation phase without the board game, gaze aversions to the table or away were associated with topic changes.

The perspectivist MapTask annotation records speaker and addressee interpretations separately (Li et al., 2026a) and has been used to evaluate whether vision-language models track common ground (Li et al., 2026b). Its reference-level labels allow gaze to be compared across repeated mentions of the same landmark. We map both corpora into one partner/task/away vocabulary and compare gaze associations across tasks and grounding measures.

3 Data and Representation

MapTask We use the gaze-annotated portion of HCRC MapTask (Anderson et al., 1991) with perspectivist labels from Li et al. (2026a), where a reference expression is *aligned* only when speaker and addressee interpretations resolve to the same landmark. Dialogues come in an eye-contact condition (ec), where participants can see each other, and a no-eye-contact condition (nc); the *up*→partner mapping is only literally partner-directed in the ec condition.

Of the corpus's 94 gaze files, 46 dialogues (31 ec, 15 nc) have gaze annotations for both participants; we match grounding annotations to landmark-reference annotations by dialogue, role, and landmark identity. After filtering windows where either participant has less than 30% gaze coverage (17 windows ruled out), we obtain 5,144 reference-expression windows: 3,807 aligned, 1,261 pending, and 76 misunderstood.

MUNDEX MUNDEX (Türk et al., 2023) records explainers (EX) teaching a board game to explainees (EE) in German. After each task, participants watched their recording: EE reported their own understanding and EX judged EE's

understanding on a four-level scale: *understood* (UND), *partially understood* (PART_UND), *not understood* (NON_UND), and *misunderstood* (MIS_UND). We combine EX judgments and EE self-reports in a pooled analysis of *annotator-judged understanding*, retaining each annotation as a separate observation with its own gaze window. In the 26 interactions with both gaze tiers, 956 valid annotations (524 EX, 432 EE) yield 807 windows (458 EX, 349 EE) after the 30% coverage filter (149 excluded): 360 UND, 199 PART_UND, 151 NON_UND, and 97 MISUND.

Gaze representation Both corpora annotate gaze as discrete behavioral categories from video, not as eye-tracking coordinates. We map both into a shared partner/task/away vocabulary: MapTask’s *up/down/off* become partner/task/away; MUNDEX’s EX/EE/TABLE/AWAY map analogously. Figure 1 shows a MapTask excerpt with both participants’ mapped gaze and two reference expressions for the same landmark. We discard gaze events with non-positive duration (annotation noise) and resolve temporal overlaps within each participant’s gaze stream. Full corpus details and window definitions are in Appendix A; the features computed from this representation are described in Section 4.

4 Experiments

Features From the shared partner/task/away vocabulary we compute gaze features per window in several groups (full definitions in Appendix B). *Raw proportions* record how much of the window each participant spends on each gaze target, plus mutual gaze (7 features in MapTask, 8 in MUNDEX). The *structured* set adds coverage, transition count, and Shannon entropy¹ (13/14 features total). Four further groups capture finer-grained patterns: (1) *temporal dynamics* capturing the timing of gaze shifts: gaze-run counts, durations, switch rate, latency, and first/last/dominant-label indicators (21 per participant); (2) *transition bigrams* encoding the direction of gaze switches: proportions of ordered label pairs such as task→partner (6 per participant); (3) *coordination* measuring whether both participants’ gaze is synchronized: joint gaze states sampled at approximately 10 Hz

¹Here, we use a duration-weighted Shannon entropy: $H = -\sum_k q_k \log_2 q_k$, where q_k is the proportion of observed gaze time directed toward canonical target $k \in \{\text{partner, task, away}\}$ within the analysis window.

(at least 20 points per window), namely mutual task and partner gaze, gaze alignment, complementary gaze, joint entropy, and partner coupling (6 joint features); and (4) *derived ratios* expressing relative gaze preferences: partner/task ratio, engagement, task dominance, and between-participant asymmetries (9 features).

Association and process analyses We use the features defined above to test whether gaze patterns differ between grounding states. Binary contrasts (Mann–Whitney U with rank-biserial correlations) compare aligned vs. non-aligned windows in MapTask and annotator-judged UND vs. non-UND in MUNDEX, stratified by interactional role and, in MapTask, by eye-contact condition, and assessed with cluster-robust logistic GEE (Liang and Zeger, 1986); q values are Benjamini–Hochberg (BH) adjusted (Benjamini and Hochberg, 1995). We also track gaze across repeated mentions of the same landmark within each dialogue to assess gaze change around alignment within speakers. Section 5 reports the main results (Table 1; Figure 2), and Appendices C–F give the full tests.

Prediction setup We also test whether the gaze features carry recoverable signal through a simple prediction task. We binarize the corpus-specific labels (aligned vs. non-aligned in MapTask; annotator-judged UND vs. non-UND in MUNDEX) because minority classes are small after intersecting with gaze coverage. All models are logistic regression (LR) with standardized features and balanced class weights. We evaluate with grouped cross-validation: 10-fold grouped by dialogue for MapTask and 5-fold grouped by explainer for MUNDEX, evaluating on held-out dialogues or explainers. We ablate each feature group and their combinations. Section 5 reports the results (Table 2), and Appendix G gives implementation details and full results.

5 Results

Associations and roles Table 1 shows the four strongest associations per corpus (full results in Tables 5–6). In both corpora, the largest associations point the same way: task-gaze proportions are higher and partner-gaze proportions lower for the positive class, while entropy and transitions tend to be higher for the negative class. Effects are small: the largest pooled $|r|$ is .058 in MapTask and .181 in MUNDEX.

Gaze change at the resolving mention

Same-speaker pairs: last non-aligned → first subsequent aligned mention (189 pairs; 45 dialogues)

Figure 2: Within-chain gaze change at the first subsequent aligned mention (189 same-speaker pairs from 45 dialogues). Panel A: mean speaker task- and partner-gaze proportions before (Pre) and after (Post) resolution; lines connect sample means, not individual trajectories; away gaze is not shown (mean < 1.5%). Panel B: standardized paired changes ($d_z = \text{mean}(\text{Post} - \text{Pre}) / \text{SD}$; paired Wilcoxon, BH-corrected) for all eight tested features; error bars are dialogue-cluster bootstrap 95% CIs (resampling dialogues to respect within-dialogue dependence); filled marker indicates $q < .05$. Only speaker gaze entropy survives correction ($q = .044$); dialogue-level aggregation does not ($q = .20$).

Corpus	Feature	Δ	r
MapTask	speaker task gaze	.033	.058
MapTask	speaker partner gaze	-.029	-.057
MapTask	speaker entropy [†]	-.046	-.054
MapTask	speaker transitions [†]	-.091	-.053
MUNDEX	EX task gaze [†]	.105	.181
MUNDEX	EX partner gaze [†]	-.102	-.172
MUNDEX	EE partner gaze [†]	-.084	-.148
MUNDEX	mutual gaze explicit [†]	-.060	-.143

Table 1: Four largest associations per corpus, selected by $|r|$. Δ : positive-class mean minus negative-class mean; r : rank-biserial correlation. All Mann–Whitney $p < .001$; [†] also significant under cluster-robust GEE (FDR $q < .05$; Appendix E). Full results in Appendix C.

In MapTask, speaker task- and partner-gaze proportions are significant in these window-level tests but not under dialogue-clustered GEE ($q = .091$); speaker entropy and transitions remain significant. With recurring participants as clusters and bias-reduced standard errors, four MUNDEX associations remain significant: the explainer’s task- and partner-gaze proportions ($q = .001$ and $q = .028$) and the explaineer’s entropy and transitions (both $q = .039$); no MapTask feature does (Appendix E).

In MapTask, associations are clearest for giver-produced references (six significant features; largest $|r|$.086), whereas follower-produced references show near-zero effects (largest $|r|$.043; Table 8). In MUNDEX, all 14 structured features have rank-biserial correlations of the same sign in EX judgments (458 windows) and EE self-reports (349). The largest effect is greater for EX judgments ($|r|$.206 vs. .151), the only stratum with features surviving correction; these include the explaineer’s gaze proportions, entropy, and transitions (Table 9). UND is the task-directed extreme across

all four gaze measures, though the remaining understanding classes do not follow a consistent order (Table 7).

All 13 MapTask features have larger $|r|$ in the eye-contact stratum than in the pooled data (largest .078 vs. .058), whereas none is significant in the no-eye-contact stratum (largest $|r|$.025), where partner-directed gaze is largely absent; the formal condition interaction is not significant (Table 10).

Gaze across the grounding process Reference chains group repeated mentions of the same landmark within a dialogue. Across chain positions, the aligned rate rises from .30 at first mentions to .59 at second mentions and .85 in the fourth-and-later bucket, and mean speaker partner gaze, entropy, and transitions are lower at second than at first mentions (Table 13).

To examine change within chains, we compare the speaker’s gaze at the last non-aligned mention with gaze at the resolving aligned mention, restricting to within-speaker pairs where the same person produced both ($n = 189$ pairs in 45 dialogues). Speaker entropy decreases significantly after BH correction ($d_z = -.20$, $q = .044$), and its dialogue-cluster bootstrap 95% CI excludes zero (Figure 2; Table 14); partner gaze, task gaze, and transitions shift in the same directions but do not survive correction. The decrease depends on the inference unit: it does not survive correction when pair differences are averaged within each of the 45 dialogues ($q = .20$), and resampling the six groups of dialogues that share participants yields a CI below zero, but the decrease is concentrated in two of these groups (Appendix F). Because later mentions are both more often aligned and more task-directed,

Feature set (macro-F1)	MapTask	MUNDEX
Majority baseline	.425	.356
LR controls only	.472	.544
LR raw proportions	.522	.564
LR structured	.512	.543
LR structured+temporal	.532	.550
LR structured+coordination	.511	.551
LR all extended	.527	.527

Table 2: Feature-group ablation (macro-F1). LR = logistic regression. “Controls only” uses condition (ec/nc) and speaker role in MapTask, and annotator role (EX/EE) in MUNDEX.

we also compare aligned and non-aligned mentions at the same chain position; only second-mention task gaze survives correction ($q=.01$; Table 15).

Prediction and ablation The two corpora favor different feature groups: structured+temporal features give the highest macro-F1 in MapTask (.532) and raw proportions in MUNDEX (.564; Table 2). These exceed controls-only scores by .060 and .020, respectively; MUNDEX structured gaze (.543) does not exceed its role-only control (.544). Across 30 reshuffled grouped partitions, these groups score highest in 27 partitions in each corpus. The gains remain modest and partition-dependent: the MapTask gain over controls ranges from .015 to .070 (mean .038), and the MUNDEX gain is positive in 29 partitions and at most .027 (Appendix G). Within the EE self-report stratum, however, four of six engineered groups score above raw proportions (Appendix A.3).

6 Discussion

Shared categories, task-specific meanings The direction of these associations is the same in both corpora, echoing map-task observations that partner-directed gaze increases around communicative difficulty (Boyle et al., 1994; Nakano et al., 2003; Murat and Vogel, 2026). The two labels measure different constructs: MapTask records referential alignment, whereas MUNDEX pools explainees’ self-reports and explainers’ judgments, so the convergence spans related but distinct grounding measures.

Which features carry predictive signal differs: temporal dynamics score highest in MapTask and raw proportions in MUNDEX. The shared categories also name gaze targets rather than functions. In MapTask, a partner glance may check a landmark reference; in MUNDEX, gaze averted from the partner has also been linked to topic changes (Lazarov and Grimmer, 2026), so it

may organize an explanation as well as reflect understanding. Comparing finer-grained referents and dialogue actions would help distinguish task-general patterns from task-specific behavior.

Gaze and interactional role Significant associations concentrate in giver-produced references and explainer judgments, whereas follower-produced references show near-zero effects. This pattern fits the task structure: givers produce the instructions being grounded, and explainers monitor explainees, whose gaze proportions and dynamics co-vary with explainers’ judgments. Feature $\times$ role interactions do not survive correction (MapTask $q=.064$; not significant in MUNDEX; Appendix D), so we report a stratum difference rather than a tested moderation, and role-conditioned modeling remains to be tested.

Implications Because the representation uses discrete behavioral categories rather than eye-tracking coordinates, it can be applied to other corpora with video-coded gaze annotations, making cross-corpus comparisons of grounding behavior easier to set up. The associations and the prediction gains over controls indicate grounding-related signal in gaze that is worth modeling together with lexical content, dialogue acts, and task state, and testing across corpora.

7 Conclusion

In collaborative tasks with asymmetric information, gaze provides directionally consistent evidence about grounding. After mapping MapTask and MUNDEX annotations into a shared partner/task/away vocabulary, aligned references and UND judgments are both accompanied by a higher share of task gaze, a lower share of partner gaze, and fewer gaze transitions, most clearly in giver-produced references and explainer judgments. In MapTask reference chains, the speaker’s gaze entropy is lower at the mention where a referent becomes aligned. These effects are small and partly depend on the unit of inference; gaze should therefore be modeled as part of the interactional state, alongside linguistic and task-context features.

8 Limitations

Representation and labels Three gaze categories cannot identify the specific landmark or object being viewed. Shared category names do not establish equivalent interactional functions across

tasks. MapTask’s up→partner mapping is literal only with eye contact; associations are detected in that stratum, but the condition interaction is not significant. MUNDEX’s retrospective self-reports and partner judgments measure different perspectives, and linked events can contribute conflicting labels: 271 of 807 rows belong to reconstructed two-perspective links, and 44 of the 135 fully retained pairs disagree on the binary label. Retaining one row per pair preserves the positive association between the explainer’s task-gaze proportion and UND (Appendix A.3).

Evidence and scope The data comprise 46 MapTask dialogues and 26 MUNDEX interactions with nine explainers, and participants recur: the MapTask dialogues involve 24 participants in six groups connected by shared participants, and eight of the nine MUNDEX explainers take part in three interactions. With these groups or explainers as GEE clusters and bias-reduced standard errors, no MapTask feature survives correction; in MUNDEX, explainer task and partner gaze and explainee entropy and transitions remain significant, whereas explainee gaze proportions and mutual gaze do not (Appendix E). The modest effects, small number of groups, sensitivity of the chain result to the inference unit, and sensitivity of prediction gains to the cross-validation partition limit conclusions about dynamic grounding and predictive generalization. Coverage filtering also restricts which moments enter the analysis, and unevenly so: two MUNDEX explainers account for 139 of the 149 excluded windows. Two asymmetric, face-to-face tasks in English and German support directional convergence; other task structures and multimodal predictors remain to be tested.

A Corpora, Annotations, and Preprocessing

A.1 HCRC MapTask

In HCRC MapTask ([Anderson et al., 1991](#)), an instruction giver guides a follower along a route using maps that deliberately differ in their landmarks. Dialogues come in an eye-contact condition (ec), where participants can see each other, and a no-eye-contact condition (nc). Gaze is annotated per participant with three categories from the corpus ontology: *up* (looking up, toward the partner when eye contact is possible), *down* (looking at the map), and *off* (looking off camera). The corpus release contains 94 gaze XML files; 46 dialogues (31 ec, 15 nc) have gaze for both participants and constitute our analysis set.

Gaze events, word timings, and landmark references live in three separate NXT annotation layers that do not reference each other directly. A landmark reference lists word IDs, so we resolve its start and end times through the timed-units layer. This yields 5,162 timed landmark references across the 46 dialogues.

The grounding labels come from the perspectivist re-annotation of [Li et al. \(2026a\)](#), which labels each reference expression (RE) as *aligned*, *pending*, or *misunderstood* depending on whether speaker and addressee interpretations resolve to the same landmark. We match grounding annotations to timed landmark references per dialogue and speaker, in order, by landmark ID; all 5,161 grounding annotations in the 46 dialogues match (100%). After the coverage filter ([Appendix A.4](#)), 5,144 windows remain: 3,807 aligned, 1,261 pending, 76 misunderstood; 3,199 ec and 1,945 nc; 3,446 giver-produced and 1,698 follower-produced.

Each observation represents an RE–landmark pair, so expressions referring to multiple landmarks can contribute observations with identical gaze windows (54 observations across 26 windows). Four windows contain both aligned and non-aligned labels for different landmarks. We test two ways of retaining one observation per window: assigning a non-aligned label if any observation in the window is non-aligned, or excluding the four conflicting windows and retaining one observation per remaining window. Both preserve the sets of significant structured features and change gaze-model macro-F1 by at most .004, although controls-only macro-F1 rises from .472 to .498–.499; the same-speaker chain pairs are unaffected.

A.2 MUNDEX

MUNDEX (Türk et al., 2023) records explainers (EX) teaching a board game to explainees (EE) in German. Afterwards, participants watched their own recording and retrospectively judged the explainee’s understanding (video-recall), giving the tiers EE_UND (explainee’s own understanding) and EX_UND (explainer’s judgment of the explainee’s understanding) with values UND, PART_UND, NON_UND, and MISUND. Gaze tiers give each participant’s gaze target (the interlocutor, TABLE, or AWAY), and a MUTUAL_GAZE tier marks mutual gaze explicitly. The release contains 45 ELAN files; 26 interactions (9 explainers) have both gaze tiers and form our analysis set. The 26 interactions contain 956 valid judgments (524 EX, 432 EE); filtering excludes 149 windows (66 EX, 83 EE). The remaining 807 annotator-judged understanding windows comprise: 360 UND, 199 PART_UND, 151 NON_UND, 97 MISUND; 349 explainee-annotated and 458 explainer-annotated.

A.3 Understanding perspectives and linked annotations

The MUNDEX target is annotator-judged understanding: UND is positive and PART_UND, NON_UND, and MISUND are negative. EX judgments of EE and EE self-reports remain separate annotation rows.

We reconstruct links from UND_MATCH=YES spans by collecting valid EX and EE annotations whose starts lie within each span expanded by 60 ms at both ends, and retaining a link only when there is exactly one candidate per perspective. Of 164 spans in gaze-complete interactions, 159 give clean links; 135 retain both rows after coverage filtering and one retains only one row, accounting for 271/807 rows (33.6%). Among the 135 retained pairs, 58 agree on the four-class label and 91 on the binary label; 44/135 (32.6%) conflict. Their median anchor separation is 4.36 s, so the paired windows need not coincide.

As a sensitivity check, retaining the EX, EE, or a seeded random row from each pair yields 672 rows. Across these variants, 11–12 of 14 structured features survive within-variant BH correction, compared with 11/14 pooled; the explainer’s task-gaze proportion remains positively associated with UND ($r = .201$ – $.229$, pooled $r = .181$). Interaction-clustered GEE and held-out-explainer

cross-validation keep linked observations within the same inference cluster and fold, respectively.

Perspective-specific prediction uses the same five-fold held-out-explainer procedure and the eight-feature raw gaze group. Raw-gaze macro-F1 is .549 versus a within-stratum majority baseline of .337 for EX judgments ($n = 458$), and .520 versus .380 for EE self-reports ($n = 349$); pooled scores are .564 versus .356 ($n = 807$). The EX/EE role indicator alone gives pooled macro-F1 .544; it is constant within a perspective. Feature-group rankings also differ by perspective: raw gaze is the highest-scoring group for EX judgments, whereas four of six engineered groups exceed it for EE self-reports (highest: structured+ratios, .556). These are point estimates from overlapping subsets of the same nine explainers.

A.4 Windows, cleaning, and coverage

MapTask windows span a reference expression plus 1.5 s of post-context, chosen to capture the addressee’s immediate reaction (confirmation, repair initiation, or gaze shift) following the expression. MUNDEX windows span an understanding annotation ± 2 s, clipped at zero; understanding annotations are short intervals (typically 1 s), so symmetric context is needed to capture gaze dynamics around the annotated moment. Gaze events with non-positive duration are discarded. For structured features, time covered by overlapping events of the same participant is counted once, so observed time cannot exceed the window; the other feature groups treat overlaps as defined in Appendix B. Giving overlapped time to the earlier event in the temporal gaze runs as well changes temporal and bigram features in 27 MapTask windows and none in MUNDEX, and no macro-F1 score by .001 or more. Coverage is the fraction of a window covered by valid canonical gaze; windows where either participant has coverage below 30% are dropped (17 MapTask and 149 MUNDEX windows). Tables 3 and 4 vary the MapTask post-reference context (0–3 s) and the MUNDEX symmetric context (1–3 s) for the LR structured model; results are stable across these ranges.

B Gaze Feature Definitions

This appendix defines each gaze feature, grouped as in Section 4. All features are computed from discrete categories of gaze behaviors, not from eye-tracking fixations.

Window (s)	n	Acc.	Macro-F1	F1 ₋
0.000	5149	0.671	0.509	0.227
1.000	5147	0.600	0.520	0.323
1.500	5144	0.571	0.512	0.342
2.000	5144	0.566	0.510	0.343
3.000	5142	0.553	0.506	0.354

Table 3: MapTask: prediction performance (macro-F1) of LR with the structured feature set under varying post-reference context lengths.

Window (s)	n	Acc.	Macro-F1	F1 ₋
1.000	804	0.544	0.543	0.536
2.000	807	0.543	0.543	0.536
3.000	807	0.549	0.549	0.552

Table 4: MUNDEX: prediction performance (macro-F1) of LR with the structured feature set under varying symmetric context lengths.

B.1 Common definitions

Windows. A window is $W = [a, b)$ with duration $T = b - a$ in seconds. For MapTask, $a = s_{\text{RE}}$ and $b = e_{\text{RE}} + 1.5$; for MUNDEX, $a = \max(0, s_{\text{UND}} - 2)$ and $b = e_{\text{UND}} + 2$. Windows are not truncated at the end of a recording, so unannotated time counts towards T but towards no gaze label.

Gaze labels. Gaze annotations are mapped to partner, task, or away. MapTask *up*, *down*, and *off* map to these categories in both visibility conditions. In MUNDEX, TABLE maps to task, AWAY to away, and EX or EE gaze targets to partner. Unassigned gaze remains missing rather than being treated as away. Events with non-positive duration are excluded.

Participants. Feature names carry a participant prefix: *spk_*/*addr_* for the speaker and addressee of the MapTask reference expression, and *ex_*/*ee_* for the MUNDEX explainer and explainee, irrespective of who provided the understanding judgment.

Observed durations. Within each window, D_k denotes the observed duration of gaze category k , and $O = \sum_k D_k$ is the total observed gaze time. Overlapping time is counted once and assigned to the earlier-starting event. These durations underlie the participant gaze proportions and structured features; gaze runs and joint sampling are defined separately below.

B.2 Raw proportions (7/8 features)

Partner, task, and away proportion (*prop_partner*, *prop_task*, *prop_away*). The share of

the window spent on each label, $p_k = D_k/T$. Because proportions are relative to the full window, they sum to coverage rather than 1.

Mutual gaze (*mutual_gaze* in MapTask, *mutual_gaze_derived* in MUNDEX). With $U_{u,\text{partner}}$ the union of participant u ’s partner-directed intervals within W ,

$$|U_{1,\text{partner}} \cap U_{2,\text{partner}}|/T.$$

It depends on partner-directed annotations alone, regardless of any overlapping task or away annotation.

Explicit mutual gaze (MUNDEX only, *mutual_gaze_explicit*). The total duration of MUTUAL_GAZE annotations within W , divided by T . In the analysed MUNDEX windows, it is nearly perfectly correlated with mutual gaze (r near 1).

The six participant proportions and mutual gaze give 7 MapTask features; explicit mutual gaze gives 8 for MUNDEX.

B.3 Structured features (13/14 features)

Structured features add three measures per participant to the raw proportions.

Coverage (*coverage*). The share of the window with an assigned gaze label, $C = O/T$. A window is retained only if both participants have $C \geq .30$.

Transition count (*transitions*). The number of label changes $\sum_{i=2}^m \mathbf{1}[k_i \neq k_{i-1}]$ between the m contributing intervals in temporal order (0 if $m < 2$). Unannotated gaps do not interrupt this sequence: different labels on either side of a gap count as a transition.

Entropy (*entropy*). Duration-weighted Shannon entropy over observed time,

$$H = - \sum_{k:D_k>0} q_k \log_2 q_k, \quad q_k = D_k/O,$$

in bits (maximum $\log_2 3$).

B.4 Temporal dynamics (21 features per participant)

Gaze runs. A gaze run is an interval assigned to a single gaze category within the analysis window. Overlapping events with the same label are combined; a later-starting event with a different label ends the preceding interval, which is not resumed afterwards. Consecutive same-label intervals separated by at most .01 s are merged, including the

intervening gap; longer gaps remain unobserved. Let the resulting runs be (s_i, e_i, k_i) , with durations $\ell_i = e_i - s_i$.

Run count (3 features). For each label k , the number of runs n_k .

Mean and maximum run duration (6 features). For each label, $\sum_{i:k_i=k} \ell_i / n_k$ and $\max_{i:k_i=k} \ell_i$ in seconds, and 0 if the label does not occur.

Switch rate (1 feature). The number of label changes between successive runs, divided by T .

Latency (2 features). For partner and task, the relative onset of the first run with that label, $(s_{\text{first},k} - a)/T$, and 1 if the label does not occur.

Dominant, first, and last label (9 features). One-hot indicators of the label with the largest total run duration, of the first run label, and of the last run label.

B.5 Transition bigrams (6 features per participant)

Bigram proportion. Repeated labels are collapsed in the sequence of run labels (Appendix B.4), including repeats separated by a gap. With n_{jk} the number of changes from j to k , each of the six ordered pairs $j \neq k$ receives

$$B_{jk} = n_{jk} / \sum_{j' \neq k'} n_{j'k'}.$$

The proportions sum to 1 if at least one change occurs and are all 0 otherwise. Like the transition count and switch rate, bigrams count changes across unannotated gaps without locating them within the gap.

B.6 Coordination (6 joint features)

Joint sampling. Gaze is sampled at approximately 10 Hz, with at least 20 equally spaced points per window. Only points at which both participants have an assigned gaze label contribute to the joint sequence J of label pairs (k_1, k_2) . All six coordination features are calculated over these jointly observed points rather than over the full window duration.

Mutual task gaze. The proportion of J with $k_1 = k_2 = \text{task}$. It indicates that both participants look at the task space, not that they inspect the same object or landmark.

Mutual partner gaze. The proportion of J with $k_1 = k_2 = \text{partner}$. Unlike mutual gaze (Appendix B.2), it is relative to jointly observed sample points rather than to the window.

Gaze alignment. The proportion of J with $k_1 = k_2$, including joint away gaze.

Complementary gaze. The proportion of J in which one participant looks at the partner and the other at the task.

Joint entropy. $-\sum_{q_{jk}>0} q_{jk} \log_2 q_{jk}$ in bits, where q_{jk} is the relative frequency of the ordered pair (j, k) in J (nine possible pairs).

Partner coupling. The Pearson correlation of the indicators $1[k_1 = \text{partner}]$ and $1[k_2 = \text{partner}]$ over J , and 0 if either is constant. It captures simultaneous coupling without a lag.

B.7 Derived ratios (9 features)

The first three ratios are computed for each participant from the raw proportions; the asymmetries compare the two participants.

Partner/task ratio. The partner proportion relative to the task proportion, with the denominator floored at .02 to avoid extreme ratios when task gaze is near zero:

$$p_{\text{partner}} / \max(p_{\text{task}}, .02).$$

Engagement. $p_{\text{partner}} + p_{\text{task}}$.

Task dominance. $p_{\text{task}} - p_{\text{partner}}$.

Partner, task, and entropy asymmetry. The absolute differences between the two participants' partner proportions, task proportions, and entropies:

$$\begin{aligned} &|p_{1,\text{partner}} - p_{2,\text{partner}}|, & |p_{1,\text{task}} - p_{2,\text{task}}|, \\ &|H_1 - H_2|. \end{aligned}$$

B.8 Feature sets, missing values, and overlaps

Feature sets. Structured features include the raw proportions. The extensions add 42 temporal, 12 bigram, 6 coordination, or 9 ratio features to the structured set (55/56, 25/26, 19/20, or 22/23 features), and all extended features combine these groups (82/83). Counts exclude the control variables of the baseline models. Association analyses use the structured features, and the reference-chain analyses a subset of them.

Missing values. Missing gaze is neither interpolated nor treated as a separate category. All extended features are defined in every analysed window.

Overlapping annotations. Overlap handling differs across duration-based measures, mutual gaze,

Feature	Pos.	Neg.	p	r
spk_prop_partner	0.166	0.196	< .001	-0.057

Table 6: MUNDEX: Mann–Whitney U tests comparing UND vs. non-UND windows. Columns as in Table 5; Pos./Neg. are UND/non-UND means.

gaze runs, and joint sampling, so feature groups can assign overlapping time differently. A sensitivity analysis applying the duration-based overlap rule to temporal and bigram features changes macro-F1 by less than .001 in both corpora (Appendix A.4).

C Full Association Tests

Tables 5 and 6 report Mann–Whitney U tests over all structured features; Table 7 reports Kruskal–Wallis tests across MUNDEX’s four understanding labels. Positive class is aligned (MapTask) and annotator-judged UND (MUNDEX); r is the rank-biserial correlation.

Feature	H	p
ex_prop_task	21.042	< .001
ex_prop_partner	19.666	< .001

ee_prop_away	2.525	0.471

Table 7: MUNDEX: Kruskal–Wallis tests across all four understanding levels (UND, PART_UND, NON_UND, MISUND). Unlike the binary Mann–Whitney tests, this preserves the four-category distinction; a significant result indicates that at least one level differs, but does not test an ordinal trend.

D Role- and Condition-Stratified Analyses

The pooled tests in Appendix C combine all windows regardless of who produced or annotated them. Here we ask whether the gaze–grounding association differs by interactional role. Tables 8 and 9 repeat the binary tests separately per role (q is BH/FDR-adjusted within each stratum). In MapTask, giver-produced references show small but statistically significant effects ($|r|$ up to .086), while follower-produced references show near-zero effect sizes ($|r| \leq .043$). The follower stratum is smaller (1,698 vs. 3,446 giver windows). Subsampling giver expressions to the follower sample size 1,000 times, without preserving dialogue-level clustering, keeps rejection rates at .887–.930, while follower effects stay near zero ($|r| \leq .024$, $p \geq .31$). A feature $\times$ role interaction in a logistic GEE for each structured feature does not survive BH correction in MapTask ($q=.064$) and is not significant in MUNDEX.

Table 10 stratifies the MapTask tests by the corpus’s visibility manipulation: in the eye-contact (ec) condition participants could see each other’s faces, while in the no-eye-contact (nc) condition a barrier prevented it. Our gaze-annotated subset contains 31 ec dialogues (3,199 windows) and 15 nc dialogues (1,945 windows). The up $\rightarrow$ partner mapping is only literally partner-directed in the ec condition. All main associations are FDR-significant in the ec stratum with slightly larger effect sizes than in the pooled analysis, while in the nc stratum partner-directed gaze largely disappears (mean

speaker partner gaze .04 vs. .25 in ec, averaged over all windows) and no feature reaches significance. This is consistent with the gaze-grounding signal coming from dialogues where partner-directed gaze is an available interactional resource, though a formal feature $\times$ condition interaction does not reach significance.

E Cluster-Robust Marginal Tests

Mann–Whitney tests treat windows as independent, although windows within a dialogue share participants and topic. To account for within-cluster dependence, Tables 11 and 12 report one logistic GEE (Liang and Zeger, 1986) per standardized feature, using exchangeable within-cluster correlation and dialogue/interaction clusters. Features significant after BH correction are marked with [†] in Table 1. We use univariate models because the structured features are strongly collinear: label proportions sum to coverage, entropy tracks transitions, and explicit and derived mutual gaze are nearly identical. Joint coefficients would therefore be difficult to interpret.

Participants also recur beyond dialogues and interactions. The 46 MapTask dialogues involve 24 participants, who form six groups of dialogues connected by shared participants; eight of the nine MUNDEX explainers take part in three interactions and one in two. We refit each GEE with these groups or with explainers as clusters. Because robust standard errors are anti-conservative with few clusters, we also apply bias-reduced (Mancl–DeRouen) standard errors (Mancl and DeRouen, 2001). With dialogue clusters, the correction leaves MapTask speaker entropy and transitions significant ($q=.009$ and $q=.010$); with participant groups, no MapTask feature survives BH correction (smallest $q=.11$; speaker entropy $q=.23$). With explainer clusters and the correction, explainer task and partner gaze ($q=.001$ and $q=.028$) and explainee entropy and transitions (both $q=.039$) remain significant, whereas explainee task and partner gaze and both mutual-gaze measures do not ($q=.055$ – $.062$). Coefficient signs do not change. The MapTask associations and the MUNDEX associations for explainee gaze proportions and mutual gaze are therefore not robust to treating recurring participants as the unit of inference.

F Reference-Chain Analyses

To examine gaze change within a dialogue, we group mentions of the same landmark concept into chains, ordered by onset: 636 chains, of which 587 have more than one mention.

Table 13 summarizes alignment and speaker gaze by mention position. For the resolution analysis (Table 14), we locate in each chain the first non-aligned mention followed by a later aligned mention of the same concept, and compare gaze at the last non-aligned mention with gaze at the resolving aligned mention (paired Wilcoxon, BH-corrected). The primary analysis restricts to same-speaker pairs, where the same person produced both mentions ($n=189$); only entropy survives correction ($q=.044$). Its standardized change is $d_z=-.20$, with a dialogue-cluster bootstrap 95% CI of $[-.34, -.07]$. As a more conservative sensitivity check, averaging pair differences within each dialogue ($n=45$) yields $q=.20$ for entropy. Resampling the six participant groups of Appendix E instead of dialogues gives a 95% CI of $[-.37, -.01]$, but the mean entropy change is $-.28$ and $-.15$ in two groups and between $-.04$ and $.01$ in the other four, and a Wilcoxon test over the six group means gives $p=.16$. The result is therefore sensitive to the inference unit. The mixed-speaker pool ($n=328$, which includes cross-speaker resolutions) is reported as an additional sensitivity check. Table 15 repeats the aligned/non-aligned contrast within each mention-position bucket.

G Prediction Setup and Full Results

As a complementary signal check, we test whether the gaze features defined in Appendix B carry enough information to predict grounding state. All classifiers are scikit-learn (Pedregosa et al., 2011) logistic regressions (standardized features, balanced class weights, `max_iter=1000`). Cross-validation is GroupKFold with 10 splits grouped by dialogue (MapTask) and 5 splits grouped by explainer (MUNDEX, held-out-explainer), so that MUNDEX test-fold performance reflects generalization to an unseen explainer. Controls are condition and speaker-role indicators (MapTask) and annotator-role (MUNDEX). Tables 16 and 17 give the full ablation with per-class F1.

These scores come from one deterministic GroupKFold partition. Repeating the controls-only model and every feature group over 30 reshuffled grouped partitions with the same numbers of folds

Role	Feature	Pos.	Neg.	p	q	r

Table 8: MapTask: Mann–Whitney tests stratified by the role that produced the reference expression. Giver-produced references ($n=3,446$) show small but statistically significant effects ($|r|$ up to .086, $q<.001$); follower-produced references ($n=1,698$) show near-zero effect sizes ($|r| \leq .043$, no $q<.05$). q : BH-corrected within each stratum.

shows how much the scores depend on the partition. In MapTask, the controls-only score ranges from .460 to .511 (mean .492); structured+temporal features score highest in 27 of the 30 partitions (all extended in the other three), and their gain over controls ranges from .015 to .070 (mean .038). In MUNDEX, the role-only control does not vary across partitions; raw proportions score highest in 27 partitions, and their gain over the control is at most .027 (mean .017) and not positive in one partition.

Table 12: MUNDEX: per-feature logistic GEE with interaction-level clustering. Columns as in Table 11; positive coefficient = higher odds of UND per SD increase.

Mention	n	Aligned rate	Spk. partner	Spk. task	Spk. entropy	Spk. trans.	Mutual
1	636	0.303	0.230	0.744	0.310	0.643	0.019
2	587	0.595	0.172	0.797	0.215	0.463	0.022
3	518	0.736	0.188	0.791	0.210	0.434	0.018
4+	3403	0.847	0.162	0.808	0.209	0.426	0.016

Table 13: MapTask: how alignment and speaker gaze evolve across repeated mentions of the same landmark. Each row is a mention position (1st, 2nd, ...); aligned rate is the proportion of mentions at that position that are aligned. Later positions generally show higher alignment and lower partner gaze, though the trend is not strictly monotonic.

Feature	Pre	Post	Δ	p	q
spk_entropy	0.355	0.263	-0.092	0.005	0.044
spk_prop_partner	0.239	0.187	-0.052	0.020	0.079

mutual_gaze	0.030	0.023	-0.007	0.445	0.529
addr_entropy	0.157	0.139	-0.018	0.463	0.529
addr_prop_partner	0.093	0.081	-0.012	0.608	0.608

Table 14: MapTask: gaze at the last non-aligned mention (Pre) vs. the first subsequent aligned mention (Post) of the same concept; same-speaker pairs only (paired Wilcoxon, $n=189$; q is BH-corrected). A separate mixed-speaker analysis ($n=328$) was examined as a sensitivity check: the four speaker features change in the same directions and all survive correction, whereas three addressee features change in the opposite direction; no addressee feature survives correction in either analysis.

4+	spk_transitions	0.422	0.453	0.605	0.708	-0.011
4+	spk_entropy	0.208	0.214	0.708	0.708	-0.008

Table 15: MapTask: aligned vs. non-aligned within each mention-position bucket (Mann–Whitney). Stratifying by position addresses the confound that later mentions are both more aligned and more task-directed. q is BH-corrected within each position bucket (4 tests per bucket). Only task-gaze proportion at second mentions survives correction ($q=.01$); first-mention contrasts are not significant (aligned rate .303).

Model / feature set	#feat.	Acc.	Macro-F1	F1 ₊	F1 ₋
