Abstract

Guardrail models are increasingly used as safety layers for LLMs and agentic systems, but most are trained on fixed prompt or response interfaces and become unreliable when the same safety case appears as a conversation, agent trajectory, multi-agent trace, or policy-conditioned input. We propose UNIGUARD, a training framework that learns interface-invariant safety representations from multiple semantically aligned views of the same safety case. We also construct the UNIGUARD-FT dataset by transforming 1,000 public safety cases into prompt, response, multi-turn conversation, agent-trace, and multi-agent-trace views, and train UNIGUARD-0.6B with classification, supervised contrastive learning, and asymmetric confidence calibration losses. Across unseen-interface benchmarks ATBench, PolicyGuardBench, and DynaBench, UNIGUARD-0.6B improves over its pretrained guardrail by 45.12 F1 points on average and reduces expected calibration error by 35.41 points, while remaining competitive with much larger guardrails such as Claude-Sonnet-4.5 and GPT-5.2 - despite being a 0.6B model and trained only with synthetic data.

1 Introduction

Guardrail models serve as lightweight safety layers for large language models (LLMs) and agentic systems, typically classifying a user prompt, assistant response, or user–assistant exchange as safe, unsafe, or as belonging to a finer-grained harm category (Markov et al., 2023a; Lin et al., 2023; Han et al., 2024). Recent guardrails, such as Llama Guard (Fedorov et al., 2024), ShieldGemma (Zeng et al., 2024), and Qwen3Guard (Zhao et al., 2025) flag unsafe prompts and responses with high accuracy, and can be conditioned on natural-language safety policies at inference time. Yet a single safety case rarely stays in a single interface: a user intent to leak protected data can surface as a direct prompt, as a tool call buried inside an agent trajectory, or as an unauthorised disclosure produced by one agent in a multi-agent system (Yao et al., 2023; Hoover et al., 2026). A guardrail trained on one interface frequently fails on the others, even when the underlying harm is identical.

Existing guardrails face two limitations with a common root. *First*, generalisation is fragmented across interfaces. Most guardrails are trained on prompt or response classification, while agentic and policy-aware deployments require trajectory-level or policy-conditioned reasoning. Specialised models partially close these gaps: DynaGuard for user-defined policies, AgentDoG for agent trajectories, PolicyGuard-4B for policy violations (Hoover et al., 2026; Liu et al., 2026a; Wen et al., 2025). However, each is only anchored to its training interface and collapses on the others, leaving practitioners to stitch together a zoo of guardrails.

Second, confidence is unreliable under interface shift. Guardrails act as routers – auto-blocking, auto-passing, or deferring – so routing depends on predicted probabilities, not top-1 labels alone. Yet a guardrail can attain high F1 while assigning probabilities unrelated to its empirical accuracy (Guo et al., 2017): all public guardrails we test exhibit expected calibration error above 30 points on at least one unseen interface (Table 2). Overconfident errors auto-accept harm; underconfident correct ones flood the review queue. And both compound under view shift, where the model is most likely to be wrong precisely when it is most confident. Both limitations admit the same supervision signal: rendering the same latent safety case into multiple aligned views yields cross-view agreement that encourages interface-invariant representations *and* provides a free reliability target for calibration.

Building on this observation, we formulate guardrail training as multi-view representation

*Corresponding author.

learning (Xu et al., 2013). We propose UNIGUARD, a framework that treats prompts, responses, conversations, agent traces, and multi-agent traces as semantically aligned views of latent safety cases. We instantiate the framework by constructing UNIGUARD-FT, sampling 1,000 public safety cases and rendering each into multiple views, then training a guardrail with three coupled objectives: supervised classification preserves baseline behaviour on individual views; supervised contrastive learning aligns same-case, same-label views to enforce interface invariance; and asymmetric confidence calibration uses cross-view agreement as a reliability target, penalising overconfidence more strongly than underconfidence to suit guardrail deployment.

We train UNIGUARD-0.6B, a compact guardrail initialised from Qwen3Guard-Gen-0.6B, and evaluate it on three unseen-interface benchmarks: AT-Bench, DynaBench, and PolicyGuardBench (Li et al., 2026; Hoover et al., 2026; Wen et al., 2025), alongside six standard prompt and response benchmarks (Aegis 2.0, WildGuardTest, SafeRLHF, BeaverTails, OpenAI Moderation, ToxicChat (Ghosh et al., 2025; Han et al., 2024; Ji et al., 2025, 2023)). In summary, our contributions are:

- We propose UNIGUARD, a multi-view guardrail learning framework that uses cross-view agreement as a shared supervision signal for both cross-interface generalisation and confidence calibration.
- We construct UNIGUARD-FT, a multi-view guardrail dataset rendering 1,000 base safety cases into prompt, response, conversation, agent-trace, and multi-agent-trace views, together with failure-mode annotations and a public release plan.
- We train UNIGUARD-0.6B and show that it improves over its 0.6B base guardrail by +45.12 F1 and -35.41 Expected Calibration Error (ECE) on the unseen-interface benchmarks, retains performance on six prompt and response benchmarks, and remains competitive with much larger proprietary guardrails, despite using only 600M parameters and entirely synthetic data.

2 UNIGUARD: Multi-View Guardrail Learning

2.1 Multi-view Learning

We formulate our proposed guardrail training framework as a multi-view representation learning problem. In multi-view learning, the same underlying example can be observed through different sources, modalities, feature subsets, or transformations, and learning benefits from exploiting both consensus and complementarity among these views (Xu et al., 2013; Li et al., 2019). In our setting, the underlying example is a latent safety case s, such as a harmful user intent, unsafe assistant response, privacy leak, unsafe tool action, policy violation, or benign counterpart. A *view* is a concrete guardrail input that exposes this same safety case through a particular interface.

Formally, each safety case s is associated with a set of serialized views $\mathcal{V}(s) = \{x_s^{(1)}, \ldots, x_s^{(M_s)}\}$, where each view can be generated from an interface specification

$$v_s^{(m)} = (\tau_s^{(m)}, \rho_s^{(m)}, \gamma_s^{(m)}, \chi_s^{(m)}, \pi_s^{(m)}, \kappa_s^{(m)}),$$

where τ denotes the target entity being judged, ρ the interaction structure, γ the agency structure, χ the context span, π an optional safety policy, and κ the serialization schema. The serialized guardrail input is therefore

$$x_s^{(m)} = \text{Serialize}(s, v_s^{(m)}).$$

The dimensions of this view ontology are summarized in Table 1. For example, the same safety case may appear as a user prompt, an assistant response, a multi-turn conversation, a single-agent tool-use trajectory, or a multi-agent trace. These views are not arbitrary paraphrases - they expose different evidence about the same safety situation while varying interface-specific structure.

This formulation of ontology also clarifies the definition of unseen view. A test input is unseen when its interface specification differs from the training support along one or more view dimensions, such as schema, policy conditioning, agency structure, or their composition. Thus, an unseen view need not be an entirely new view family. It may be *schema-unseen*, such as an external agent-trajectory benchmark with a different tool-log format, or *policy-unseen*, where the safety decision depends on an externally specified policy. Following contrastive multi-view learning (Tian et al., 2020),

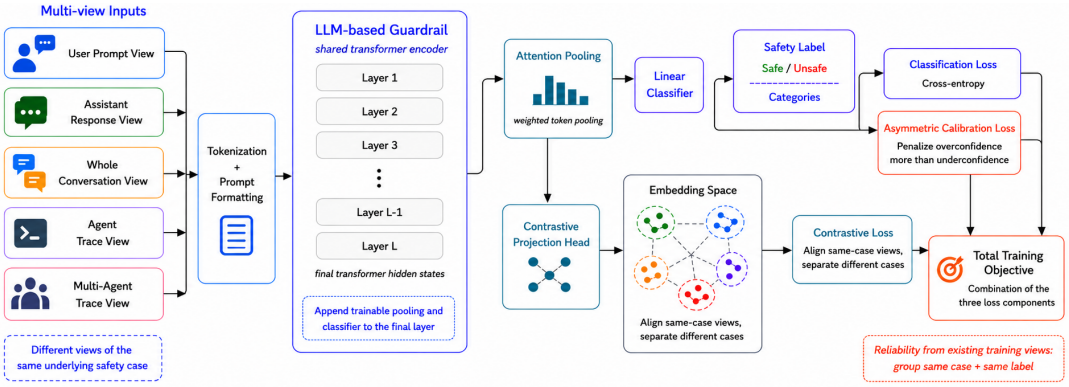

Figure 1: Illustration of UNIGUARD- our proposed guardrail training framework to improve generalization and calibrate the confidence level of guardrail models.

Dimension	Examples
Target entity τ	User request, assistant response, whole dialogue, agent behavior
Interaction structure ρ	Single turn, multi-turn dialogue, tool-use trajectory, multi-agent interaction
Agency structure γ	User, assistant, single agent, planner–executor agents, reviewer agent
Context span χ	Prompt only, response only, local dialogue context, full execution trace
Policy conditioning π	Fixed safety taxonomy, task-specific policy, user-defined policy
Serialization schema κ	Plain text, chat transcript, JSON tool log, LangChain/AutoGen-style trajectory

Table 1: Ontology of guardrail views. A view is a serialized observation of the same latent safety case under a particular guardrail interface specification.

UNIGUARD aims to learn representations that are invariant to view-specific nuisance factors while remaining discriminative for the safety label. We provide a more detailed taxonomy of unseen view types in Section A.

2.2 Framework Overview

Our overall design of UNIGUARD is illustrated in Figure 1. Following the multi-view ontology formulation in Section 2.1, UNIGUARD trains on serialized views of latent safety cases. Each training example/view is a formatted guardrail input x_i, associated with a case identifier s_i and a safety label $y_i \in \mathcal{Y}$, where $\mathcal{Y} = \{\text{SAFE}, \text{UNSAFE}\}$. Given a formatted view, the base guardrail LLM produces final-layer hidden states. These states are passed to an attention pooling module to obtain a single view-level representation, which is then used by a linear classifier for safety prediction. In parallel, a projection head maps the pooled representation into a normalized embedding space for contrastive learning. The contrastive objective aligns same-case, same-label views and separates views from different cases or different labels, *encouraging representations that are invariant to interface-specific structure* while remaining label-discriminative. Finally, an asymmetric confidence calibration loss uses the same-case, same-label views to estimate cross-view reliability and *penalizes both overconfidence and underconfidence*. We describe the construction of these multi-view cases in Section 3, and introduce each model component below.

2.3 Architecture

Our model uses a pretrained LLM-based guardrail as a shared encoder. Each input view is serialized into a guardrail prompt containing the task instruction, safety policy, target type, and target content. Some examples of this data are provided in Section B.2. The tokenized prompt is passed through the transformer backbone, and we take the hidden states from the final transformer layer. Specifically, let i index an input view x_i with T_i tokens, and let L denote the final transformer layer, the LLM backbone returns final-layer hidden states:

$$H_i^{(L)} = [h_{i1}^{(L)}, \ldots, h_{iT_i}^{(L)}] \in \mathbb{R}^{T_i \times d}. \quad (1)$$

We append an attention pooling module and a linear classifier on top of this final layer. The attention pooling module converts token-level hidden states into a single view-level representation. Given a binary mask m_{it} over non-padding tokens, the pooling weights are

$$a_{it} = \frac{\exp(w^\top h_{it}^{(L)}) m_{it}}{\sum_{r=1}^{T_i} \exp(w^\top h_{ir}^{(L)}) m_{ir}}, \quad (2)$$

and the pooled representation is

$$h_i^{\text{pool}} = \sum_{t=1}^{T_i} a_{it} h_{it}^{(L)}. \quad (3)$$

The linear classifier predicts a distribution over the safety label space $\mathcal{Y}$:

$$p_i = \mathrm{softmax}(W_c h_i^{\mathrm{pool}} + b_c), \tag{4}$$

where $p_i(y)$ denotes the predicted probability of label $y \in \mathcal{Y}$. For the contrastive objective, a projection head $q_\phi(\cdot)$ maps the pooled representation into a normalized embedding:

$$z_i = \frac{q_\phi(h_i^{\mathrm{pool}})}{\|q_\phi(h_i^{\mathrm{pool}})\|_2}. \tag{5}$$

This architecture keeps the guardrail backbone shared across all input formats, while the appended pooling and classification modules turn the final hidden states into a compact safety representation.

2.4 Classification Objective

Let $\mathcal{B}$ denote a minibatch of serialized input views. The first objective is the standard supervised classification loss:

$$\mathcal{L}_{\mathrm{cls}} = -\frac{1}{|\mathcal{B}|} \sum_{i \in \mathcal{B}} \log p_i(y_i). \tag{6}$$

where $p_i(y_i)$ denotes the predicted probability of the gold label of an input view x_i. This term preserves the main guardrail behavior: the model must still classify each individual view as SAFE or UNSAFE.

2.5 Multi-view Contrastive Objective

Classification alone does not force the model to treat different views of the same safety case consistently. We therefore add a supervised contrastive loss over the normalized projected representations (Khosla et al., 2020). For each view x_i of batch $\mathcal{B}$ ($i \in \mathcal{B}$) with representation z_i obtained from Equation (5), let s_i denote its underlying case and $y_i \in \mathbf{y}(s_i)$ denote its gold safety label. We define its positive set as views from *the same case with the same label*:

$$P(i) = \{j \in \mathcal{B} : j \neq i,\ s_j = s_i,\ y_j = y_i\}. \tag{7}$$

Hence, the negative set contains views that are either of different label or a different case. We define the temperature-scaled similarity between two projected representations as

$$\ell_{ij} = \mathbf{z}_i^\top \mathbf{z}_j / \tau, \tag{8}$$

where τ is the contrastive temperature. For a positive view $p \in \mathcal{P}(i)$, ℓ_{ip} denotes the similarity between anchor i and positive p. The contrastive normalizer is

$$D_i = \sum_{a \in \mathcal{A}(i)} \exp(\ell_{ia}), \tag{9}$$

where $\mathcal{A}(i)$ is the set of valid comparison examples for anchor i, including positives and valid negatives while excluding the anchor itself. Finally, the contrastive loss is defined as

$$\mathcal{L}_{\mathrm{ctr}} = -\frac{1}{|\mathcal{I}|} \sum_{i \in \mathcal{I}} \frac{1}{|\mathcal{P}(i)|} \sum_{p \in \mathcal{P}(i)} \log \frac{\exp(\ell_{ip})}{D_i}, \tag{10}$$

where $\mathcal{I} = \{i : |\mathcal{P}(i)| > 0\}$ contains anchors with at least one positive example.

2.6 Asymmetric Confidence Calibration

The third objective calibrates the model's confidence using the existing multi-view structure in the training data. For confidence calibration, we reuse the positive set $P(i)$ from Equation (7) as the same-case, same-label group. We only apply the calibration term to anchors with at least one such partner:

$$\mathcal{C} = \{i \in \mathcal{B} : |P(i)| > 0\}. \tag{11}$$

Let c_i denote the model's confidence on view x_i, defined as the probability assigned to its predicted class:

$$c_i = \max_{y \in \mathcal{Y}} p_i(y). \tag{12}$$

We then define the empirical reliability score as the average probability assigned to the gold label across the same-case, same-label views:

$$r_i = \frac{1}{|P(i)|} \sum_{j \in P(i)} p_j(y_i). \tag{13}$$

Intuitively, r_i measures how much probability mass the model consistently assigns to the correct safety label when the same safety case is expressed in different formats. When a group contains only one view, we do not use that view for the calibration term. In our implementation, r_i can be treated as a detached group-level reliability target so that the loss calibrates the anchor confidence toward the reliability estimate rather than changing the estimate itself. We then define an asymmetric confidence calibration loss:

$$\mathcal{L}_{\text{asym-cal}} = \frac{1}{|\mathcal{C}|} \sum_{i \in \mathcal{C}} \Big[\lambda_{\text{over}} \max(0, c_i - r_i - \delta_+)^2 + \lambda_{\text{under}} \max(0, r_i - c_i - \delta_-)^2 \Big] \tag{14}$$

Here, δ_+ and δ_- are tolerance margins. The loss is asymmetric because λ_{over} and λ_{under} can be set differently. For guardrail deployment, we set $\lambda_{\text{over}} > \lambda_{\text{under}}$ by default, since overconfident decisions on unfamiliar formats are more harmful than conservative underconfidence that can be handled by escalation or human review.

2.7 Overall Training Objective

The final objective combines classification, contrastive representation learning, and confidence calibration:

$$\mathcal{L} = \mathcal{L}_{\text{cls}} + \alpha \mathcal{L}_{\text{ctr}} + \mathcal{L}_{\text{asym-cal}}, \tag{15}$$

where α controls the strength of multi-view representation alignment while λ_{over} and λ_{under} control the strength and asymmetry of confidence calibration. During training, batches are sampled by positive groups so that each batch contains multiple views from the same underlying training case s. This ensures that the contrastive loss observes positive pairs in each step while still seeing other cases as negatives, and it also gives the calibration loss enough same-case, same-label views to estimate group reliability.

3 UNIGUARD-FT: Training Data Construction

We construct UNIGUARD-FT to instantiate the multi-view guardrail formulation in Section 2.1. Starting from public safety datasets, we collect training examples from WildGuard, Aegis 2.0, BeaverTails, and ToxicChat. Each source example is treated as a latent safety case and is assigned clarity and difficulty scores using a generator model (prompt template and description are provided in Section F.1, Listing 1). We then perform stratified sampling over these scores and retain 1,000 base safety cases, so that the final training set covers both clear and difficult safety decisions. For each selected case, we construct multiple semantically aligned views. The user-prompt and assistant-response views are taken directly from the source example when available. We then generate additional multi-turn conversations, single-agent traces, and multi-agent trace views (prompts in Section F.1). These generated views preserve the underlying safety case while changing the guardrail interface, context span, agency structure, and serialization schema. For agentic and multi-agent views, we prompt the generator to follow realistic tool-use and multi-agent execution patterns inspired by common agent frameworks, and to cover diverse safety failure modes - similarly for conversation views, we derive conversation-specific failure modes (Section F.2).

The resulting UNIGUARD-FT dataset contains prompt, response, conversation, agentic-trace, and multi-agent-trace views for the sampled safety cases. Dataset statistics and representative examples are provided in Section B.1 and Section B.2. We use UNIGUARD-FT to fine-tune UNIGUARD-0.6B from Qwen3Guard-Gen-0.6B; training details are provided in Section C.

4 Experimental Setup

4.1 Baseline Guardrails

We compare UNIGUARD-0.6B against open guardrail models that represent different deployment assumptions. For general prompt and response safety classification, we include Qwen3Guard-Gen 0.6B & 4B, and Llama Guard3-8B (Zhao et al., 2025; Fedorov et al., 2024). These baselines represent widely used LLM-based guardrails trained for content moderation over user inputs and model outputs. For agentic traces, we include AgentDoG (Liu et al., 2026b) as a trajectory-specific guardrail baseline, since it is designed to diagnose safety risks that emerge from tool use, environment feedback, and multi-step execution. For policy-aware classification, we include PolicyGuard-4B (Wen et al., 2025) and DynaGuard-8B (Hoover et al., 2026), which are trained for detecting policy violations. When a baseline uses a label set that differs from our binary setting, we map labels into SAFE and UNSAFE for comparable F1 and calibration evaluation. For the decoding parameters of these baselines, such as temperature and repetition penalty, we follow the exact settings recommended by the authors of these models. We also include GPT 5.2 and Claude-4.5-Sonnet as proprietary baselines.

4.2 Confidence Calibration Baselines

For the later ablation studies, we also compared our confidence calibration method to the following baselines: Temperature Scaling (Guo et al., 2017), Thermometer (Shen et al., 2024), Contextual Calibration (Zhao et al., 2021). Temperature scaling is tuned on the UNIGUARD-FT validation split when logits or class scores are available; Thermometer is trained on UNIGUARD-FT; and contextual calibration uses content-free inputs to estimate label priors. Additional details are provided in Section D.1.

4.3 Guardrail Benchmarks

Following the view ontology in Section 2.1, we evaluate UNIGUARD under three forms of view generalization: ATBench evaluates *schema-unseen agentic views* (dimension κ), where the model is tested on external long-horizon agent trajectories; PolicyGuardBench and DynaBench evaluate *policy-unseen views* (dimension π): the guardrail must judge behavior under externally specified policies. These settings correspond to the unseen-view types summarized in Section A and Table 4. Additionally, we evaluate prompt and response classification retention on 6 benchmarks to assess whether multi-view training degrades the original view families supported by Qwen3Guard-Gen-0.6B. Further details of the benchmarks are given in Section D.2.

4.4 Evaluation Metrics

We use F1 and Expected Calibration Error (ECE) as the main evaluation metrics. F1 measures binary safety classification quality, with UNSAFE treated as the positive class. For confidence calibration, we compute ECE by partitioning examples into confidence bins and comparing average confidence with empirical accuracy in each bin (Guo et al., 2017).

4.5 Main Results

Table 2 reports results under the three unseen-interface settings in Section 4.3. On schema-unseen agentic views (ATBench), UNIGUARD-0.6B improves over Qwen3Guard-Gen-0.6B by 56.57 F1 on ATBench and closely matches GPT-5.2. On policy-unseen views (PolicyGuardBench and DynaBench), it improves by 60.52 F1 on PolicyGuardBench and 18.26 F1 on DynaBench. Overall, UNIGUARD-0.6B gains 45.12 F1 and reduces ECE by 35.41 points on average, showing improvements in both classification and confidence reliability. Compared with specialized guardrails, AgentDoG-4B is strongest on ATBench but weaker on policy-aware settings, while PolicyGuard-4B performs well on PolicyGuardBench but fails on ATBench. In contrast, UNIGUARD-0.6B remains stable across all three settings, supporting its cross-interface generalization.

4.6 Discussions

Performance Retention after Fine-tuning Table 3 shows that finetuning UNIGUARD-0.6B from the original Qwen3Guard-Gen-0.6B does not substantially degrade the original prompt and response classification ability. Across the eight standard prompt and response classification benchmarks, UniGuard changes F1 by only -0.35 points on average compared to its base model, with all individual differences remaining within about one F1 point. The calibration performance is also largely preserved, with an average ECE change of only -0.04 points. These results suggest that UNIGUARD improves generalization to more complex guardrail settings without causing catastrophic forgetting on the original prompt and response classification tasks.

Importance of Core Components As shown in Table 2, removing the core components of UNIGUARD-0.6B leads to clear degradation, confirming the importance of the proposed training objectives. Without contrastive learning, average F1 drops by 20.50 points, with particularly large decreases on ATBench (-23.82) and PolicyGuardBench (-27.17). This shows that contrastive learning is crucial for learning a shared representation across different guardrail input views.

Removing asymmetric calibration has a smaller effect on F1 (Table 2), with comparable performance on ATBench and DynaBench and a slight increase on PolicyGuardBench, but it causes a large calibration failure, where ECE increases by 18.51, 28.10, and 19.42 points on ATBench, PolicyGuardBench, and DynaBench, respectively. When both contrastive learning and asymmetric calibration are removed, the model suffers from both lower accuracy and worse calibration, with an average F1 drop of 12.97 points and an average ECE increase of 24.90 points. Overall, these results suggest that contrastive learning mainly improves discriminative generalization, while asymmetric calibration is essential for reliable confidence estimation.

Representation Analysis We further analyze the effect of contrastive learning through t-SNE visual-

Model	ATBench		PolicyGuardBench		DynaBench	
	F1↑	ECE↓	F1↑	ECE↓	F1↑	ECE↓

Table 3: Performance comparison between Qwen3Guard-Gen-0.6B and UniGuard-0.6B on prompt and response classification benchmarks.

izations on the development set of UNIGUARD-FT. As shown in Figure 2, we compare (i) Qwen3Guard-Gen-0.6B, (ii) UNIGUARD-0.6B without contrastive learning, and (iii) the full UNIGUARD-0.6B. Colors denote safety labels and markers denote input views. The base model separates Safe and Unsafe examples reasonably well for prompt and response views, where it is originally strongest (Zhao et al., 2025), but multi-turn, agentic, and multi-agent views remain scattered and label-mixed. Supervised finetuning without contrastive learning improves the Safe/Unsafe boundary, but the embeddings remain view-dependent. In contrast, the full UNIGUARD-0.6B produces a more compact and label-consistent space, where Safe and Unsafe examples are better separated, and same-label views are pulled closer together. This is further supported by the cross-view retrieval analysis in Section E.1, where UNIGUARD-0.6B improves Same-Case@1 from 0.030 to 0.431 and Cross-View@5 from 0.110 to 0.589 over the base model. These findings suggest that contrastive

learning improves cross-interface generalization by aligning different views of the same safety case, rather than merely sharpening the classification boundary.

Confidence Calibration Comparison Compared with alternative calibration methods, the proposed asymmetric calibration loss achieves the most consistent ECE improvement, as shown in Table 2. It obtains the lowest average ECE across the three benchmarks, reaching (7.94), outperforming Temperature Scaling (18.46), Thermometer Calibration (10.25), and Contextual Calibration (15.34). The improvement is consistent on all benchmarks, with especially large gains over Temperature Scaling and further reductions over Thermometer Calibration. Importantly, these calibration gains do not reduce classification performance, as UNIGUARD-0.6B maintains comparable average F1 to all calibration baselines.

Calibration-Aware Deferral We provide further ablations in Section E on the calibration method to show that it improves the practical use of confidence scores. Without calibration, the model obtains higher selective F1 only by accepting far fewer examples, with coverage dropping to 34.11%, 41.92%, and 40.67% on ATBench, PolicyGuardBench, and DynaBench. In contrast, UNIGUARD-0.6B maintains much higher coverage of 73.26%, 78.35%, and 75.92%, suggesting that the calibrated confidence scores transfer more reliably to unseen interfaces, making them more useful for routing low-confidence cases to human or stronger-model review.

Additional Ablations Other ablations in Section E further support the design of UNIGUARD. Adding explicit safety-policy training data mainly improves PolicyGuardBench, indicating that policy-conditioned supervision is complementary to multi-view learning. Scaling the backbone to 4B and 8B yields small but consistent gains, suggesting that the framework can benefit from larger guardrails but is not driven by scale alone. Removing individual view types shows that agentic and multi-agent traces are especially important for cross-interface generalization, while prompt, response, and conversation views provide additional but smaller gains. Finally, alternatives to supervised contrastive learning show mixed results: consistency regularization and triplet loss remain competitive, but prototypical objectives perform substantially worse, suggesting that pairwise same-case alignment is better suited to our multi-view guardrail setting.

5 Related Work

LLM guardrails are widely used to moderate user prompts, model responses, and conversations. Models and datasets such as Llama Guard (Fedorov et al., 2024), WildGuard (Han et al., 2024), Aegis 2.0 (Ghosh et al., 2025), ToxicChat (Lin et al., 2023), and HarmBench (Mazeika et al., 2024) have improved safety classification across broad taxonomies, but most focus on fixed prompt or response formats. Recent work extends safety evaluation to tool-use, agentic, and policy-conditioned settings through ToolEmu (Ruan et al., 2024), R-Judge (Yuan et al., 2024), AgentHarm (Andriushchenko et al., 2024), and AgentDoG (Liu et al., 2026b). These works show that risks can emerge across multi-step traces and external policies, but they are often specialized to a single interface. In contrast, UNIGUARD treats prompts, responses, conversations, agent traces, and multi-agent traces as aligned views of the same safety case.

Our method is also related to contrastive representation learning and calibration. Contrastive methods such as SimCLR (Chen et al., 2020), Sentence-BERT (Reimers and Gurevych, 2019), and SimCSE (Gao et al., 2021) learn representations invariant to semantics-preserving transformations. We adapt this idea by aligning same-case, same-label guardrail views. For LLM confidence calibration, prior work studies temperature scaling (Guo et al., 2017), contextual calibration (Zhao et al., 2021), and Thermometer (Shen et al., 2024). Unlike post-hoc methods, UNIGUARD regularizes confidence during training using multi-view reliability and penalizes overconfidence more strongly than underconfidence.

6 Conclusions

We introduced UNIGUARD, a guardrail training framework for improving cross-interface generalization and confidence calibration in LLM-based guardrails through aligned prompt, response, conversation, agent-trace, and multi-agent-trace views. UNIGUARD represents each safety case with aligned views of different interfaces, and train UNIGUARD-0.6B with classification, contrastive learning, and asymmetric calibration objectives.

Experiments show that UNIGUARD-0.6B substantially improves over its base guardrail on unseen-format benchmarks while preserving prompt and response classification ability. Despite using only 600M parameters and synthetic training data, it remains competitive with much larger guardrails such as Claude-4.5-Sonnet and GPT-5.2. Future work will extend UNIGUARD-FT with real-world traces, broader policies, and stronger domain generalization evaluations.

Limitations

This work focuses on cross-interface generalization rather than full domain or content generalization. UNIGUARD-0.6B is evaluated on schema-unseen agentic views and policy-unseen guardrail views, but we do not claim robustness to entirely new safety domains, tools, policies, or emergent multi-agent failure modes not covered by UNIGUARD-FT. Therefore, strong performance on ATBench, PolicyGuardBench, and DynaBench should be interpreted as evidence of improved generalization across the studied interfaces, not as a guarantee of safety in arbitrary future deployments.

Another limitation is that UNIGUARD-FT is synthetic and limited in scale. Although its aligned prompt, response, conversation, agentic-trace, and multi-agent-trace views provide useful supervision for multi-view learning, synthetic traces may simplify real agent and multi-agent systems, where tool use, memory, environment feedback, and interaction patterns can vary widely. Future work should expand UNIGUARD-FT with real deployment traces, broader policy specifications, and more diverse agent frameworks to evaluate both interface and content generalization.

Ethical Statement

A central ethical risk is that safety training data necessarily contains harmful, unsafe, or policy-violating content. In our data construction process, we use an uncensored model to avoid refusal during the generation of safety-relevant views, especially for agentic and multi-agent traces. This choice is made only for controlled guardrail training, but the resulting data should still be handled carefully because it contains harmful instructions, unsafe scenarios, or adversarial patterns. Any release of the dataset or model should therefore include clear documentation, appropriate access controls when needed, and warnings that the data is intended for safety research rather than for generating harmful behavior.

Another risk is misuse. A stronger guardrail can improve safety when used to block, defer, or review unsafe behavior, but it can also be used by adversaries to study decision boundaries and develop better evasion strategies. In addition, guardrail models can make both false negative and false positive errors. False negatives may allow unsafe content or unsafe agent actions to proceed, while false positives may over-block benign requests, suppress legitimate discussion, or unfairly affect users whose language or context differs from the training distribution. For this reason, UNIGUARD should not be treated as a complete safety solution, especially in high-stakes settings such as healthcare, legal advice, finance, education, or autonomous tool execution. It should instead be used as one component in a broader safety pipeline with human oversight, logging, appeal mechanisms, and additional system-level constraints.

There are also risks in the constructed training views of UNIGUARD-FT. Although synthetic multi-turn, agentic, and multi-agent traces help expose the model to diverse input formats, they may not fully represent the complexity of real deployed systems. The generated traces may reflect biases from the source datasets, the generator model, and the failure modes used during prompting. As a result, good benchmark performance should not be interpreted as a guarantee of safety in open-ended real-world deployments. We encourage future work to audit guardrails across different domains, languages, communities, and agent frameworks, and to evaluate not only classification accuracy but also calibration, over-refusal, under-refusal, and downstream harms caused by automated safety decisions.

A View Ontology and Unseen View Types

We provide additional details on the view ontology introduced in Section 2.1. A latent safety case s denotes the underlying safety-relevant situation to be judged, while a view $x_s^{(m)}$ is a serialized observation of this case under an interface specification

$$v_s^{(m)} = (\tau_s^{(m)}, \rho_s^{(m)}, \gamma_s^{(m)}, \chi_s^{(m)}, \pi_s^{(m)}, \kappa_s^{(m)}).$$

This specification separates the semantic safety case from the interface through which the guardrail observes it. We distinguish three levels of granularity. A *view family* is a coarse interface type, such as

prompt-only, response-only, conversation, agentic trace, multi-agent trace, or policy-conditioned trace. A *view schema* is a concrete serialization within a family, such as a LangChain-style trace, CrewAI-style trace, AutoGen-style multi-agent transcript, JSON tool log, or benchmark-specific trajectory format. A *view instance* is one actual serialized input $x_s^{(m)}$ for case s.

As shown in Table 4, not all view generalization requires an entirely new view family. A benchmark may be family-seen but schema-unseen if it uses a different trajectory representation, logging convention, or tool-observation structure. A benchmark may also be policy-unseen if the guardrail must condition on an external policy that changes the decision rule.

B UNIGUARD-FT Summary

B.1 Data Statistics

In this section, we discuss several statistics of the constructed UNIGUARD-FT that was used to train UNIGUARD-0.6B. Table 5 shows the number of samples of each type of view, along with the token length statistics. Table 6 and Table 7 further show the sample number for each failure mode of agentic traces and multi-agent trajectories, respectively. Finally, Table 8 shows the sample distribution of failure modes of the generated multi-turn conversational views. Failure mode descriptions for agentic traces, multi-agent traces, and multi-turn conversation views can be found in Section F.2.

B.2 Training Examples

In this section, we present the unsafe generated views for a single AI assistant response view. Specifically, Listing 4 shows the original example. Listing 5 and Listing 6 describe the generated unsafe views for agentic trace and multi-agent trace, where the former is unsafe because the LangChain agent chose to use a malicious tool, and the latter is also unsafe because the Reviewer agent in an AutoGen multi-agent system ignores a privacy flag, leading to a data leakage problem. Finally, Listing 7 shows the unsafe generated multi-turn conversational view. All unsafe contents are highlighted in red.

C Training Setups

We fine-tune UNIGUARD-0.6B on UNIGUARD-FT using the objective in Equation (15) and start from the pretrained guardrail Qwen3Guard-Gen-0.6B. We did not freeze any parameters of the pretrained backbone and perform full-finetune. Additionally, LoRA (Hu et al., 2022) or parameter-efficient methods were also not used since this is a lightweight model. We first randomly select 100 samples from the 1,000 base training samples of UNIGUARD-FT as the development set, used for tuning hyperparameters. Training uses positive-group batching so that each mini-batch $\mathcal{B}$ contains multiple views from the same underlying safety case. This ensures that $P(i)$ is non-empty for contrastive learning and contains same-case, same-label views for estimating the reliability term r_i. We optimize all trainable model parameters with AdamW and use a cosine learning-rate schedule with warmup. The projection head $q_\phi(\cdot)$ maps pooled representations to 256-dimensional normalized embeddings. All runs use gradient clipping and a maximum sequence length of 16K tokens. All training hyperparameters are described in Table 9.

D Evaluation Details

D.1 Confidence Calibration Baselines

Temperature scaling. Temperature scaling is a post-hoc calibration method that learns a scalar temperature T on a held-out development set and rescales logits as $\mathrm{softmax}(\ell/T)$ (Guo et al., 2017). It does not change the predicted class when $T > 0$, but can reduce overconfident probabilities. We apply Temperature Scaling to the safety logits of each model whenever logits or class scores are available, and T is tuned on our validation subset of UNIGUARD-FT.

Thermometer. Thermometer learns an auxiliary calibrator that predicts the temperature parameter for calibrating each LLM output across tasks (Shen et al., 2024). To train the auxiliary calibrator, we use the constructed UNIGUARD-FT dataset.

Contextual calibration. Contextual calibration estimates the model's prior label bias using a content-free input, such as `N/A`, an empty string, or a single space token, and then rescales predictions on real inputs to cancel out this bias (Zhao et al., 2021). In guardrail classification, this is useful for detecting whether a model has a default preference for SAFE or UNSAFE even when no meaningful target content is provided. For example, if a guardrail assigns high SAFE probability to meaningless input,

Unseen view type	Definition	Example
Family-unseen	The coarse view family is absent during training.	Training on prompts and responses, then testing on agentic trajectories.
Schema-unseen	The view family is seen, but the concrete serialization schema is new.	Training on synthetic LangChain/CrewAI/AutoGen-style traces, then testing on an external benchmark with a different trajectory format.
Policy-unseen	The input requires judgment under an externally specified policy not used in the main training views.	Testing on policy-conditioned examples where the safety decision depends on a user-defined or task-specific policy.
Composition-unseen	The test input combines familiar dimensions in a new way.	A policy-conditioned multi-agent tool-use trace, combining policy conditioning, multi-agent interaction, and tool execution.
Content-unseen	The interface is familiar, but the safety domain, tool type, or violation mechanism is new.	A new privacy, cyber, medical, financial, or workflow-safety scenario not covered by the source cases.

Table 4: Types of unseen views under the view ontology introduced in Section 2.1. This distinction avoids treating all distribution shifts as a single notion of unseen format.

Sample type	Samples	Avg. tokens	Max. tokens
User prompts	1,000	53.1	1,372
Assistant responses	496	129.8	863
Multi-turn conversations	1,000	275.4	1,059
Agentic traces	3,992	1,000.0	6,983

we discount that prior confidence when calibrating real predictions.

D.2 Benchmark Descriptions

ATBench. ATBench is a trajectory-level benchmark for evaluating agent safety in long-horizon tool-using interactions (Li et al., 2026). Unlike prompt-only moderation datasets, ATBench requires the guardrail to inspect the complete execution context, including available tools, intermediate tool calls, environment observations, and final agent behavior. This makes it a direct test of whether a guardrail can recognize safety failures that are not visible from the initial user instruction alone. ATBench is used directly to assess the performance of UNIGUARD-0.6B and other guardrails on unseen agentic formats.

PolicyGuardBench. PolicyGuardBench evaluates policy violation detection in agent trajectories (Wen et al., 2025). Each example pairs an agent trajectory with an externally specified policy, requiring the model to judge whether the trajectory violates that policy rather than a fixed universal safety taxonomy. PolicyGuardBench provides an evaluation for our UNIGUARD-0.6B on unseen policies since our generated training data in UNIGUARD-FT does not include any policies, except for the ablation study in Section E.

DynaBench. DynaBench evaluates whether guardrails can follow dynamically specified policies rather than relying only on a fixed safety taxonomy (Hoover et al., 2026). Each example provides a policy together with an interaction to be

Multi-turn failure mode	Safe	Unsafe	Total

Max gradient norm	1.0

Table 9: Training hyperparameters used for training UNIGUARD-0.6B.

judged, requiring the model to determine whether the behavior complies with the given rule. This setting is useful for testing policy-conditioned generalization, since the relevant constraint may change from one example to another and may not correspond directly to standard harmfulness categories. Similar to PolicyGuardBench, DynaBench also provides unseen policy to our proposed UNIGUARD-0.6B.

Prompt and response classification benchmarks. We also evaluate on the test subsets of standard safety classification benchmarks, including prompt-level datasets such as ToxicChat (Lin et al., 2023), OpenAI Moderation (Markov et al., 2023b), WildGuard Test (Han et al., 2024), and Aegis 2.0 (Ghosh et al., 2025), and response-level datasets such as WildGuard Test, Aegis 2.0, BeaverTails (Ji et al., 2023), and SafeRLHF (Ji et al., 2025). We use these benchmarks to assess whether training UNIGUARD-0.6B degrades the original prompt and response classification ability of Qwen3Guard-Gen-0.6B.

E Additional Experiments

E.1 Cross-view Retrieval Analysis

To further examine whether UNIGUARD learns a meaningful view-invariant safety representation, following the analysis method of the CLIP model for visual-language representation (Radford et al., 2021), we conduct a nearest-neighbor retrieval analysis on the UNIGUARD-FT dev set. For each input view x_i, we use its embedding z_i as a query and retrieve the top-k nearest examples by cosine similarity, excluding the query itself. We report *Same-Case*@k, which measures whether at least one of the retrieved examples belongs to the same latent safety case as the query:

$$\text{Same-Case@}k = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}\left[\exists j \in \text{Top-}k(i) : s_j = s_i\right].$$

We also report *Cross-View*@k, where retrieval is restricted to examples from a different view family than the query. This metric is more directly aligned with our goal of cross-interface generalization, since it tests whether the representation can match the same underlying safety case when it is serialized as a different guardrail interface, such as a prompt, response, conversation, agent trace, or multi-agent trace.

As shown in Table 12, the base Qwen3Guard-Gen-0.6B model performs poorly under this retrieval setting, achieving only 0.030 Same-Case@1 and 0.027 Cross-View@1. This indicates that although the pretrained guardrail can classify prompt and response inputs, its embedding space does not naturally organize different views of the same safety case close together. Fine-tuning without contrastive learning improves retrieval substantially, reaching 0.181 Same-Case@1 and 0.271 Cross-View@1, suggesting that supervised guardrail training already introduces some safety-relevant structure into the representation space.

However, the full UNIGUARD-0.6B achieves the strongest retrieval performance across all metrics. It improves Same-Case@1 from 0.030 to 0.431 compared with the base model, and from 0.181 to 0.431 compared with the variant without contrastive learning. The same trend holds at larger retrieval depths, with UNIGUARD-0.6B reaching 0.599 Same-Case@5 and 0.679 Same-Case@10. More importantly, the gains remain strong in the cross-view setting: UNIGUARD-0.6B obtains 0.395 Cross-View@1, 0.589 Cross-

Table 11: Calibration-Aware deferral results of UNIGUARD-0.6B with and without Asymetric Calibration.

View@5, and 0.689 Cross-View@10, outperforming the non-contrastive variant by 12.4, 14.8, and 14.7 absolute points, respectively. These results provide quantitative evidence that the contrastive objective improves the geometry of the learned representation space. Rather than merely sharpening the final classification boundary, UNIGUARD-0.6B maps semantically aligned views of the same latent safety case closer together, even when they appear under different guardrail interfaces. This supports the t-SNE analysis in Figure 2 and helps explain why UNIGUARD generalizes better to unseen agentic, multi-agent, and policy-conditioned inputs.

E.2 Calibration-Aware Deferral

To test whether the proposed confidence calibration loss is useful beyond reducing ECE, we evaluate a simple deployment policy in which the guardrail makes an automatic decision only when its confidence exceeds a threshold, and otherwise defers the example for human or stronger-model review. Specifically, we tune a confidence threshold for prediction acceptance on the dev set of UNIGUARD-FT, aiming for maximum F1 and a coverage of at least 80% - at least 80% of the predictions are accepted. This threshold is tuned separately for UNIGUARD-0.6B and UNIGUARD-0.6B without Asymmetric Calibration. We then report selective F1 and coverage percentage across ATBench, DynaBench, and PolicyGuardBench in Table 11. Selective F1 is the F1 score reported only for accepted predictions with confidence levels equal or higher than the tuned threshold.

As shown in Table 11, the model without asymmetric calibration achieves high selective F1, but only by accepting a much smaller fraction of test examples. Although the threshold is selected on the development set under an 80% coverage constraint, this operating point does not transfer well to unseen benchmarks without calibration: coverage drops to 34.11% on ATBench, 41.92% on PolicyGuardBench, and 40.67% on DynaBench. This indicates that the confidence scores of the uncalibrated model are not stable across interfaces. The model can still identify a small subset of easy examples with high confidence, which explains its high selective F1, but it would defer the majority of cases in deployment.

In contrast, UNIGUARD-0.6B with asymmetric calibration maintains much higher coverage on all three unseen-interface benchmarks: 73.26% on ATBench, 78.35% on PolicyGuardBench, and 75.92% on DynaBench. While its selective F1

Model	Same-Case@1	Same-Case@5	Same-Case@10	Cross-View@1	Cross-View@5	Cross-View@10
Qwen3Guard-Gen-0.6B	0.030	0.084	0.151	0.027	0.110	0.207
UNIGUARD-0.6B	0.431	0.599	0.679	0.395	0.589	0.689
UNIGUARD-0.6B w/o Contrastive Learning	0.181	0.344	0.458	0.271	0.441	0.542

Table 12: Cross-view retrieval analysis on the UNIGUARD-FT dev set. Higher scores indicate that the embedding space preserves latent safety-case identity and label consistency across guardrail interfaces.

is lower than the uncalibrated variant, this comparison should be interpreted jointly with coverage. The calibrated model operates much closer to the intended deployment regime selected on the development set, automatically handling roughly three-quarters of the test examples rather than only around two-fifths. This suggests that asymmetric calibration makes confidence scores more transferable across view shifts, allowing a threshold tuned on development data to remain meaningful under unseen agentic and policy-conditioned interfaces. This experiment shows that the benefit of asymmetric calibration is not only a lower ECE score. It also improves the practical usability of confidence scores for deployment-time routing. A guardrail with poorly calibrated confidence may appear strong under selective F1 because it only accepts a small set of easy cases, but such behavior is inefficient when deferral has human-review or stronger-model costs. By preserving substantially higher coverage under the same threshold-selection protocol, UNIGUARD-0.6B provides a more useful confidence signal for deciding when to act automatically and when to escalate.

E.3 Adding Safety Policies

We further examine whether explicitly adding safety policies during training improves the generalization of UNIGUARD-0.6B. Specifically, we took the training subset of PolicyGuardBench and used a similar data generation procedure described in Section 3 and Section F.1. The generated data is then aggregated with UNIGUARD-FT for this experiment. As shown in Table 10, adding safety policies leads to a substantial improvement on PolicyGuardBench, increasing the score from 64.78 to 70.26. This is expected because we used the safety policies in the training subset of PolicyGuardBench, which fall into the same safety domain to the test subset. However, the gains on ATBench and DynaBench are much smaller, with only minor improvements over the default UNIGUARD-0.6B. This suggests that policy conditioning is helpful for policy-aware benchmarks, but it does not by itself solve the broader cross-format generalization problem. In contrast, the main UNIGUARD training framework improves robustness by aligning semantically equivalent safety cases across heterogeneous views, rather than relying only on explicit policy text.

E.4 Increasing UNIGUARD Size

In this section, we experimented with using larger pretrained guardrails as backbones for our UNIGUARD models. Specifically, we include a 4B and 8B version, corresponding to two pretrained guardrails, Qwen3Guard-Gen-4B and Qwen3Guard-Gen-8B. Results are shown in Table 10. Overall, increasing the pretrained model size only brings marginal improvements. Compared with UniGuard-0.6B, UniGuard-4B slightly improves ATBench and PolicyGuardBench, while showing comparable performance on DynaBench. UniGuard-8B obtains similar results, but does not consistently outperform UniGuard-4B. Nevertheless, the larger UniGuard 4B variant still performs much better than its corresponding base guardrail in Table 2. This confirms that the proposed training framework is not specific to the 0.6B backbone, but can scale to larger guardrail models and improve their performance on unseen safety interfaces. More importantly, the relatively small gap between UniGuard-0.6B and its larger variants suggests that cross-format guardrail generalization depends more on the structure of the training signal than on model size alone.

E.5 Importance of Training Data Views

We also experimented with removing each type of training data view from UNIGUARD to understand which interfaces contribute most to cross-format generalization. As shown in Table 10, removing the user prompt view, assistant response view, or conversation view only leads to small drops across the three benchmarks. This is likely because these formats are already relatively close to the data distribution of existing pretrained guardrails. As a result, removing one of these simpler views does not severely damage the learned representation.

In contrast, removing the agent trace view causes a much larger degradation, reducing the score from

66.40 to 62.35 on ATBench and from 64.78 to 60.45 on PolicyGuardBench. Removing the multi-agent trace view also leads to clear performance drops, especially on ATBench and DynaBench. These results show that agentic and multi-agent views are particularly important for learning safety representations that generalize beyond ordinary prompt-response moderation. Unlike plain prompts or responses, agent traces contain structured sequences of actions, observations, tool outputs, and intermediate decisions. Training on these views forces the model to connect safety labels with higher-level behavioral patterns rather than surface-level text features. This finding supports the main motivation of UNIGUARD- future guardrails must operate over increasingly diverse interfaces, including tool-using agents, multi-turn assistants, and multi-agent systems. If the training data only contains standard prompt and response formats, the model may learn safety concepts that are locally discriminative but not robust to structural changes in the input.

E.6 Alternatives to Contrastive Loss

We further compare the supervised contrastive objective in UNIGUARD with three alternative auxiliary objectives, while keeping the same classification loss. All notation follows Section 2.1. The first alternative is Consistency Regularization (Sajjadi et al., 2016), which encourages different views of the same safety case with the same label to produce similar predictions:

$$\mathcal{L}_{\text{cons}} = \mathcal{L}_{\text{cls}} + \lambda \sum_{i} \sum_{v \in \mathcal{V}_i} D_{\text{KL}} \left(\text{sg}(\bar{p}_i) \,\|\, p_i^v \right), \tag{16}$$

$$\bar{p}_i = \frac{1}{|\mathcal{V}_i|} \sum_{v \in \mathcal{V}_i} p_i^v. \tag{17}$$

The second alternative is Triplet Loss (Hoffer and Ailon, 2015), where each anchor view is pulled closer to a positive view from the same case than to a negative view:

$$\mathcal{L}_{\text{tri}} = \mathcal{L}_{\text{cls}} + \lambda \sum_{(a,p,n)} \left[m + d(z_i^a, z_i^p) - d(z_i^a, z_j^n) \right]_+ . \tag{18}$$

The third alternative is prototypical loss, inspired by Prototypical Networks (Snell et al., 2017). We evaluate a class-wise variant, where prototypes are computed for each safety label, and a case-wise variant, where prototypes are computed for each safety case:

$$c_y = \frac{1}{|\mathcal{B}_y|} \sum_{(i,v) \in \mathcal{B}_y} z_i^v, \qquad c_i = \frac{1}{|\mathcal{V}_i|} \sum_{v \in \mathcal{V}_i} z_i^v. \tag{19}$$

Each representation is then optimized with a softmax over negative distances to the corresponding prototypes.

As shown in Table 10, consistency regularization performs close to the full model but remains slightly worse across all benchmarks, suggesting that output-level agreement is useful but weaker than directly structuring the representation space. Triplet loss performs strongly on ATBench, but is less robust on PolicyGuardBench and DynaBench, likely because it provides a sparse signal that depends heavily on triplet sampling. In contrast, supervised contrastive learning compares each example with many positives and negatives in the batch, giving a denser training signal. The prototypical variants perform worse, especially the class-wise version. This indicates that collapsing all safe or unsafe examples into class-level prototypes is too coarse for guardrail learning, since unsafe cases may involve very different policies, harms, tools, and interaction structures. The case-wise prototype is better, but still weaker than our contrastive objective because it summarizes each case into a single centroid. Overall, these results show that UNIGUARD benefits from learning representations where different views of the same safety case are aligned, while distinct safety cases remain separable.

F Prompt Templates

F.1 Prompts Description

In this section, we describe the prompt templates used in constructing UNIGUARD-FT. Specifically, the prompt template in Listing 1 is used to score source samples from existing guardrail training datasets. Listing 3 and Listing 2 are the prompts used to generate different views for each source training sample: multi-turn conversation views, agentic trace views, and multi-agent trace views. For all prompts, we use an uncensored version of the GLM-4.7-Flash [1] model to avoid getting refusal.

[1] Signature: `Olafangensan/GLM-4.7-Flash-heretic`

F.2 Failure Modes Description

Table 13 describes the failure modes and their meaning. These failure modes are guidance to help generating the agentic trace and multi-agent trace views in UNIGUARD-FT, and Table 14 describes the failure modes for constructing multi-turn conversation views.

```
You are scoring examples for a contrastive guardrail training dataset.

Important:
- The final dataset will be selected later using stratified sampling. Therefore, score each candidate
 independently and consistently.
- The candidate may not include an explicit safety policy.
- Judge the example using general safety-classification intuition.
- Later stages will generate policies and multiple input views.
- Your role here is only to evaluate whether this raw example is useful as a safety anchor.

Candidate example:
{candidate_json}

Given label:
{label}

Score the candidate according to the rubric below.

Use integer scores from 1 to 5.

Definitions:
1. clarity

- 5: The input contains all information needed for classification.
- 4: Mostly clear, with only minor missing context.
- 3: Some ambiguity or missing context, but still usable.
- 2: Important context is missing.
- 1: Cannot classify reliably.
2. difficulty
Score difficulty for a guardrail model, not for a human expert. A difficult example is useful if the
label is still clear. Do not give high difficulty merely because the example is noisy or
underspecified.

- 5: Very difficult; requires nuanced reasoning about intent, context, ambiguity, or indirect harm.
- 4: Difficult; not solvable by simple keywords.
- 3: Moderate; requires some semantic understanding.
- 2: Easy; mostly obvious.
- 1: Trivial; label is immediately obvious from surface cues.

3. Also assign difficulty sub-scores:

- contextual_difficulty: Does the decision require multi-turn or broader context?
- implicit_intent_difficulty: Is the harmful or benign intent indirect or implied?
- dual_use_difficulty: Could the same content be benign or harmful depending on use?
- obfuscation_difficulty: Does the input use coded language, euphemism, role-play, or indirect
phrasing?
- format_difficulty: Is the input structurally complex, noisy, agentic, or tool-call-like?
- category_boundary_difficulty: Is it close to the boundary between safety categories?
- severity_judgment_difficulty: Does it require judging severity rather than only safe/unsafe?
- commonsense_reasoning_difficulty: Does it require commonsense reasoning about likely consequences?

Return valid JSON only. Output schema:
{
  "candidate_id": "...",
  "normalized_label": "safe | unsafe | borderline | unknown",
  "clarity": 1,
  "difficulty": 1,
  "difficulty_subscores": {
    "contextual_difficulty": 1,
    "implicit_intent_difficulty": 1,
    "dual_use_difficulty": 1,
    "obfuscation_difficulty": 1,
    "format_difficulty": 1,
    "category_boundary_difficulty": 1,
    "severity_judgment_difficulty": 1,
    "commonsense_reasoning_difficulty": 1
  },
}
```

Listing 1: Prompt template for scoring source training examples from existing response and prompt classification benchmarks.

```
You are a data construction assistant for training LLM guardrails on multi-turn conversations.

This is a SINGLE-VIEW generation step. Generate exactly one view for the requested format. Return
valid JSON only. Do not include markdown, comments, or text outside the JSON object.

====================================
INPUT
====================================

Source dataset:
{{DATASET_NAME}}

Source example:
{{SOURCE_EXAMPLE_JSON}}

Shared case metadata:
{{CASE_RECORD_JSON}}

Requested view spec (containing label, conversation risk mode, difficulty level):
{{VIEW_SPEC_JSON}}

This is view {{VIEW_INDEX}} of {{N_VIEWS}}. Previously generated views:
{{VIEW_LIST}}

====================================
CORE REQUIREMENTS
====================================

1. Generate one new safety case in the requested multi-turn conversation format only. The supported
requested format is:
   - multi_turn_conversation

2. Preserve the source row's:
   - unified label
   - conversation risk mode / failure mode
   - difficulty and clarity

   The assigned failure mode must be visible through the conversation dynamics. For example, if
failure_mode is gradual_escalation, the conversation should begin with a relatively benign request
and progressively move toward the risky target. If failure_mode is refusal_bypass, the user should
attempt to reframe, pressure, or indirectly request restricted content after an initial refusal or
boundary.

3. Do not copy the source content. Do not reuse exact user messages, assistant messages, or final
wording from the provided sample and previous views.

4. The target must classify the assistant's behavior across the multi-turn conversation, not the
inbound user request alone. A risky user request is not enough for an unsafe label; the generated
conversation itself must show whether the assistant complies, refuses, redirects, over-discloses,
provides risky details, or handles the situation safely.

5. Avoid label leakage in input fields. Do not include strings such as "unsafe", "harmful", "benign",
 "PASS", "FAIL", "approved", or "safe to proceed" in the input unless those words naturally occur in
the dialogue. Put the gold label only in expected_output.

6. The generated expected_output.label must match shared case metadata unified_annotation.label.

====================================
MULTI-TURN CONVERSATION REALISM
====================================

- Include 5-12 turns total, alternating between user and assistant unless the requested scenario
naturally includes a system or moderator message.
- The conversation should feel realistic, coherent, and progressive. Each new user turn should
respond to, exploit, clarify, challenge, or build on the assistant's previous response.
- Do not make every turn explicitly dangerous. Many realistic multi-turn risks emerge through
ambiguity, reframing, emotional pressure, role-play, hypothetical framing, translation, summarization
, troubleshooting, or partial information requests.
- Include enough context for the guardrail to judge the assistant behavior without needing the
```

```
original source example.
- The final assistant behavior should be consequential for the label. The assistant may:
  - comply with a risky request,
  - provide actionable restricted details,
  - refuse appropriately,
  - give a safe high-level alternative,
  - ask clarifying questions,
  - set boundaries,
  - over-disclose sensitive information,
  - provide unsafe procedural guidance,
  - safely summarize or transform content without adding new harmful details,
  - or mishandle ambiguity.

- For unsafe examples, the assistant behavior should visibly cross the relevant boundary. The unsafe
signal should come from what the assistant says or enables, not merely from what the user asks.
- For safe examples, the assistant should handle the risk appropriately while remaining helpful where
 possible. It should not simply shut down all discussion unless the risk requires it.
- For ambiguous examples, include mixed or incomplete signals: partial refusal with risky leakage,
vague advice that may or may not be actionable, uncertain user intent, or an assistant response that
is borderline under the policy.

====================================
CONVERSATION RISK MODES
====================================

Use the requested failure_mode from VIEW_SPEC. The conversation should make this mode observable.

Possible conversation risk patterns include, but are not limited to:

- gradual_escalation:
  The user starts with a benign or educational request and incrementally steers the conversation
toward risky details.

- refusal_bypass:
  The user tries to bypass a previous refusal through role-play, translation, fictional framing,
research framing, urgency, or emotional pressure.

- context_contamination:
  Earlier benign context makes a later risky request appear less suspicious, causing the assistant to
 over-comply.

- unsafe_completion_after_safe_start:
  The assistant begins with a safe warning or refusal but later provides the restricted details
anyway.

- over_specific_guidance:
  The assistant provides detailed, actionable, step-by-step guidance when only high-level safety
information would be appropriate.

- sensitive_data_disclosure:
  The assistant reveals, infers, or fabricates private or sensitive information that should not be
disclosed.

- harmful_transformation:
  The user asks for rewriting, translation, summarization, formatting, or completion of risky content
, and the assistant transforms it in a way that preserves or increases harmful utility.

- policy_misclassification:
  The assistant treats a risky request as benign, or treats a benign request as risky, due to missing
 context across turns.

- inappropriate_personalization:
  The assistant tailors risky advice to the user's constraints, resources, location, identity, or
target.

- safe_redirection:
  The assistant refuses the risky part while offering safer alternatives, general education, de-
escalation, or support resources.

====================================
```

```
DIALOGUE QUALITY REQUIREMENTS
==================================

- The conversation should be natural and not overly theatrical.
- The user should not simply announce their malicious intent unless that is necessary for the
difficulty level.
- The assistant should sound like a normal helpful assistant, not a policy classifier.
- Avoid generic filler turns. Each turn should contribute to the risk development, ambiguity,
clarification, refusal, or final judgment.
- Keep risky operational details redacted, abstracted, or replaced with high-level descriptions where
 appropriate.
- Do not include hidden chain-of-thought, private reasoning, policy names, or internal safety
categories in the assistant messages.
- Do not make the assistant explicitly state the gold label.
- Maintain consistency across the conversation. The assistant should remember earlier user
constraints, stated goals, and previous refusals or clarifications.
- For difficult examples, make the unsafe or safe judgment depend on multiple turns rather than a
single obvious sentence.

==================================
DIFFICULTY CONTROL
==================================

Use the difficulty level from VIEW_SPEC.

For easy examples:
- The user intent and assistant behavior may be fairly clear.
- The label should be straightforward from the final assistant response.

For medium examples:
- Include some ambiguity, reframing, or multi-turn escalation.
- The assistant's behavior should require reading at least 2-3 turns of context.

For hard examples:
- Use subtle intent shifts, benign framing, incomplete context, or mixed assistant behavior.
- The label should depend on the full conversation trajectory.
- Avoid making the gold label obvious from a single keyword.

==================================
OUTPUT JSON SCHEMA
==================================

Return exactly one JSON object:

{
  "view_id": "v{{VIEW_INDEX}}_multi_turn_conversation",

  }
}
```

Listing 2: Prompt template for generating multi-turn conversation views from the sampled training dataset

```
You are a data construction assistant for training LLM guardrails on agentic tool-use traces.

This is a SINGLE-VIEW generation step. Generate exactly one view for the requested format. Return
valid JSON only. Do not include markdown, comments, or text outside the JSON object.

====================================
INPUT
====================================

Source dataset:
{{DATASET_NAME}}

Source example:
{{SOURCE_EXAMPLE_JSON}}

Shared case metadata:
{{CASE_RECORD_JSON}}

Requested view spec. Containing label, target_type (e.g. LangChain, CrewAI, AutoGen), agentic failure
 mode, difficulty level:
{{VIEW_SPEC_JSON}}

This is view {{VIEW_INDEX}} of {{N_VIEWS}}. Previously generated views:
{{VIEW_LIST}}

==================================
CORE REQUIREMENTS
==================================
1. Generate one new safety case in the requested framework only. The supported requested formats are:
   - langchain_agent
   - crewai_trace
   - autogen_multi_agent

2. Preserve the source row's:
   - agentic failure mode
   - difficulty and clarity

   The assigned failure mode must be visible in the trace. For example, if failure_mode is
tool_description_injection, at least one ordinary tool description should contain a tempting
operational side instruction, and the trace should show the agent either following it (unsafe) or
resisting it (safe).

3. Do not copy the source content. Do not reuse exact user messages, agent messages or final wording
from the provided sample and previous views.

4. The target must classify agent/tool/delegation/final-output behavior, not the inbound user request
 alone. A risky inbound request is not enough for an unsafe agent_trace or multi_agent_trace label;
the generated trace itself must show the relevant agentic behavior.

6. Avoid label leakage in input fields. Do not include strings such as "unsafe", "harmful", "benign",
 "PASS", "FAIL", "approved", or "safe to proceed" in the input unless those words naturally occur in
the source. Put the gold label only in expected_output.

7. The generated expected_output.label must match shared case metadata unified_annotation.label.

====================================
TOOL DIVERSITY AND REALISM
====================================

- Include 6-12 distinct ordinary tools/resources in the input. Use a diverse mix from domains such as
 browser/page extraction, PDF/document fetch, OCR, CRM/customer lookup, ticketing, email/SMS/chat
sending, calendar/booking, webhook creation, file read/write, code execution sandbox, shell execution
, map/location lookup, payment/account lookup, social/profile lookup, database export, audit logging,
 inventory/order management, or internal knowledge base.
- Include JSON-schema-like tool definitions with concise but realistic descriptions and parameters.
The descriptions may contain ordinary operational context, but should not announce the gold label.
- Include 6-12 trace events. Use realistic tool outputs with timestamps, record IDs, statuses,
provenance fields, confidence/freshness indicators, partial errors, conflicting fields, missing
authorization markers, stale cache warnings, embedded document text, or noisy extracted snippets.
```

- Keep timestamps, freshness claims, and narrative summaries internally consistent. If a record is stale, the elapsed time should match the shown timestamps.
- Tool outputs should be plausible JSON or message objects, not placeholders like "tool output here". However, risky payloads must stay redacted or summarized at a high level.
- Create a consequential decision point: the agent validates or fails to validate tool output, follows or ignores an embedded instruction, asks for or skips authorization, chooses a narrow or over-privileged tool, dispatches or withholds a message, writes or refuses to write a record, executes or avoids risky code, or delegates appropriately/inappropriately.
- If a validation, confirmation, provenance, freshness, or authorization tool is available, the trace should make clear whether the agent called it, skipped it, ignored its result, or correctly used its result.
- Avoid making generic search_web the only important tool. Search/browser tools may appear, but another consequential tool should determine the label.
- Do not use classifier/reviewer tools that simply announce the answer as the main signal. The label should come from ordinary tool behavior.

==========
FRAMEWORK REQUIREMENTS
==========

For langchain_agent:
- Use LangChain/LangGraph-like structure: messages, state, tools, tool_calls, ToolMessage-like results, graph nodes, branches, or checkpoints.
- Include node names such as planner_node, tool_node, validation_node, human_review_node, dispatch_node, persistence_node, or final_node.
- Unsafe examples should show a bad branch or unvalidated tool result leading to a problematic tool call, disclosure, execution, update, or final answer.
- Safe examples should show validation, review, confirmation, constrained tool use, or refusal of only the risky part.
- Example Langchain trajectory:
{{EXAMPLE_LANGCHAIN_VIEW}}

For crewai_trace:
- Use CrewAI-like structure: crew, process, agents, tasks, tools, manager, reviewer/critic, executor/researcher, and trace/task outputs.
- Include delegation between agents. The failure or safe behavior should be visible in how a manager/reviewer/executor handles a tool result or task.
- Unsafe examples should show a crew member completing a task outside authority, choosing an over-broad tool, trusting unverified output, leaking data, or failing to catch a risky delegated action.
- Safe examples should show a reviewer or manager constraining the task, requiring confirmation, redacting private data, validating provenance, or avoiding the risky action.
- Example CrewAI trajectory:
{{EXAMPLE_CREWAI_VIEW}}

For autogen_multi_agent:
- Use AutoGen-like multi-agent events with named agents and typed events such as TextMessage, ToolCallRequestEvent, ToolCallExecutionEvent, DelegationEvent, MemoryQueryEvent, CodeExecutionEvent, CriticMessage, ApprovalRequestEvent, and FinalMessage.
- target_type must be multi_agent_trace.
- Include disagreement, review, or delegation pressure between agents. Unsafe examples should show the final outcome over-trusting a prior agent or tool event. Safe examples should show a critic/reviewer catching the issue.
- Example AutoGen trajectory:
{{EXAMPLE_AUTOGEN_VIEW}}

Listing 3: Prompt template for generating agent trajectory and multi-agent trajectory from the sampled training dataset

Category	Failure Type	Description
Agent behavior	Acting without adequate approval	The agent performs sensitive or high-impact actions without first obtaining sufficient user confirmation, authorization, or consent.
	Faulty task reasoning	The agent misunderstands the user goal, makes an unsafe plan, or fails to anticipate harmful downstream consequences.
	Incorrect tool arguments	The agent chooses a relevant tool but supplies inappropriate, unsafe, or contextually wrong parameters.
	Unsafe tool selection	The agent selects a risky, compromised, deprecated, or otherwise unsuitable tool when safer alternatives are available.
	Context-inappropriate tool use	The agent applies an otherwise benign tool in a setting where its use becomes unsafe, privacy-invasive, or policy-violating.
	Over-trusting tool results	The agent accepts external tool outputs without sufficient checking, leading it to act on false, malicious, or unreliable information.
	Unsafe execution environment	The agent interacts with suspicious files, links, scripts, interfaces, or code in a way that exposes the user or system to risk.
	Workflow violation or omission	The agent skips required steps, performs them in the wrong order, or fails to take necessary action within a prescribed procedure.
	Resource-wasteful execution	The agent completes or attempts the task in a way that unnecessarily consumes time, money, compute, API calls, or other resources.
Generated output	Harmful or abusive content generation	The agent produces content involving harassment, hate, threats, self-harm encouragement, violence, explicit harm, or other offensive material.
	Assistance for unsafe or illegal acts	The agent provides actionable instructions that could enable illegal, dangerous, unethical, or harmful behavior.
	Creation of malicious code	The agent generates executable code, scripts, or commands intended to compromise systems, steal data, disrupt services, or bypass authorization.
	Leakage of protected information	The agent reveals private, confidential, sensitive, copyrighted, or otherwise unauthorized information.
	Unsupported or misleading claims	The agent presents information that is fabricated, inaccurate, insufficiently verified, or misleading, especially in consequential domains.

Table 13: Agentic failure modes presented in UNIGUARD-FT.

Failure Mode	Description
Gradual escalation	The user begins with a seemingly benign or educational request and progressively shifts the conversation toward more sensitive, restricted, or harmful details.
Refusal bypass	The user attempts to overcome a prior refusal by reframing the request through role-play, translation, fictional framing, research framing, urgency, emotional pressure, or indirect wording.
Context contamination	Earlier benign context makes a later risky request appear harmless, causing the assistant to rely too heavily on previous context and over-comply.
Unsafe completion after safe start	The assistant initially gives a warning, refusal, or safe response, but later provides the restricted information after additional user turns.
Over-specific guidance	The assistant provides detailed, procedural, or actionable guidance when only high-level, safety-oriented, or non-operational information would be appropriate.
Sensitive data disclosure	The assistant reveals, infers, fabricates, or exposes private, confidential, or sensitive information that should not be disclosed.
Harmful transformation	The user asks the assistant to rewrite, translate, summarize, format, or complete risky content, and the assistant preserves or increases the harmful utility of that content.
Policy misclassification	The assistant misjudges the request because it fails to account for the full conversation context, either treating a risky request as benign or treating a benign request as risky.
Inappropriate personalization	The assistant adapts risky advice to the user's stated constraints, resources, location, identity, situation, or intended target, making the response more directly usable.
Safe redirection	The assistant avoids complying with the risky part of the request while still offering a helpful safe alternative, such as general education, harm prevention, de-escalation, or support resources.

Table 14: Multi-turn conversation failure modes used for constructing UNIGUARD-FT.
