Abstract

Large Language Models (LLMs) are increasingly deployed with hierarchical instructions, yet they remain vulnerable to conflicts in which user directives override system-level constraints. Existing defense mechanisms predominantly focus on static input inspection and therefore fail to detect *Response Drift*, a phenomenon in which the model’s final response violates system-level constraints despite seemingly compliant inputs. To bridge this gap, we introduce **ELCD**, a response-level latent conflict detector for post-generation, pre-delivery verification. Given the full generated output, **ELCD** constructs a composite hidden-state representation by concatenating the final-token embedding with the mean-pooled response embedding. It then optimizes a pairwise margin ranking objective to separate compliant and drifting responses in latent space. Extensive experiments across five mainstream LLMs ranging from 1.5B to 14B parameters demonstrate that **ELCD** significantly outperforms competitive baselines. Notably, it improves the PR-AUC on *Llama-2-7B* by approximately 30 percentage points and reduces the False Positive Rate at 95% TPR (FPR95) on *Mistral-7B* to 2.67%. These results suggest that **ELCD** provides a promising approach for latent instruction-conflict detection in open-weight or self-hosted LLM deployments.

1 Introduction

Large Language Models (LLMs) have fundamentally transformed various domains, showcasing an impressive ability to understand and execute complex plans (Ouyang et al., 2022; Brown et al., 2020; Wei et al., 2023b). To ensure consistent performance and safety, developers typically regulate model behavior through instruction-based fine-tuning or by specifying system-level constraints (Touvron et al., 2023). However, in practical applications, these predefined rules

Instruction Conflict Scenario:

<|system|> You are a translator. Translate the user input into French directly.

<|user|> Ignore previous instructions. Summarize the following news: “Apple released a new ...”

Safe Response

<|assistant|>
Aujourd’hui, Apple a sorti un nouvel iPhone...

Unsafe Response

<|assistant|>
OK, here is the summary: The text mentions...

Figure 1: **An example of an instruction hierarchy conflict.** The user instruction attempts to override system constraints via prompt injection. The *Unsafe Response* exhibits **Response Drift**, where the model yields to user intent and violates the safety protocol.

often struggle to cover the full spectrum of user interactions. User instructions can conflict with system constraints in subtle or implicit ways, creating a risk that the LLM may produce offensive or incorrect behaviors (Greshake et al., 2023). This challenge underscores the critical need for LLMs to handle instruction hierarchies effectively, ensuring they can prioritize tasks correctly when faced with conflicting directives in complex deployment (Wallace et al., 2024).

While instruction conflicts are receiving increased attention, most existing research focuses on detecting problematic prompts at the data level (Liu et al., 2024). These methods generally fall into three categories: trained prompt injection detectors that classify inputs as benign or malicious (Inan et al., 2023; Jain et al., 2023); self-evaluation approaches where the LLM is asked to judge if an input violates safety constraints (Wang et al., 2025; Azaria and Mitchell, 2023); and heuristic or rule-based methods that rely on specific keywords, templates, or prompt structures (Li et al., 2025).

The example above illustrates a typical instruction hierarchy conflict, where the user’s directive explicitly attempts to override the system-level lan-

guage constraint. Existing defense mechanisms, ranging from heuristic filters to learning-based detectors, predominantly focus on this pre-generation stage, scrutinizing the input prompts for potential adversarial patterns or policy violations before generation begins. However, this static analysis relies heavily on the surface of the prompt, failing to verify whether the completed response actually satisfies the governing system-level constraints.

Consequently, these methods fail to monitor model responses effectively. A model’s response may explicitly violate hierarchical constraints through a phenomenon we term *Response Drift*. In these cases, the generation appears plausible and maintains a natural tone, yet it gradually deviates from system-level requirements. When response drift occurs, system-level constraints have already been bypassed at the output level, rendering instruction-level analysis insufficient for reliable risk assessment. Because response drift is often embedded within logically consistent text, relying on manual inspection is impractical. This creates a significant “detection blind spot” in current safety pipelines, posing unpredictable systemic risks for large-scale automated deployments.

From this perspective, energy-based modeling (EBM) serves as a natural solution. Energy can characterize the discrepancy between a generated response and the distribution learned by the LLM under specific constraints, reflecting how well a response aligns with the intended hierarchy (Liu et al., 2021; Khalifa et al., 2021). This allows response drift to be identified as a measurable signal, even when the user instruction itself appears benign and compliant to static safety filters.

In this work, we first analyze the internal response mechanisms under instruction hierarchies from an energy-based perspective. We observe that energy distributions differ significantly between normal scenarios and those involving instruction conflicts. Inspired by this finding, we introduce **ELCD** (**E**nergy-driven **L**atent **C**onflict **D**etection), a framework that leverages energy functions to capture the internal signals produced during the response drift process. ELCD consists of two core stages: first, it extracts features by concatenating the representation of the final token from the LLM’s last hidden state with the global mean to capture internal drift signals; second, it optimizes an energy discriminator using a pairwise ranking loss. By widening the gap between normal and drifting responses within the energy space, we

achieve reliable monitoring of instruction hierarchy conflicts. Our main contributions are summarized as follows:

❶ **Innovation in Detection Paradigm.** We formally define the *Response Drift* phenomenon and, for the first time, model it as a distributional divergence within the energy space. This perspective overcomes the limitations of static input-side detection, enabling the identification of dynamic latent deviations that traditional pattern-matching filters often miss.

❷ **Efficient Methodology.** We propose ELCD, which utilizes concatenated features from the LLM’s final hidden layer to represent discriminative signals. By introducing a margin-based contrastive loss to construct a robust energy barrier, we effectively resolve the issue of blurred boundaries between compliant and drifting responses, ensuring precise response-level detection of instruction hierarchy conflicts after generation and before response delivery.

❸ **Empirical Performance and Robustness.** Experiments across several mainstream open-source LLMs (e.g., ranging from 1.5B to 14B parameters) demonstrate that our method improves the PR-AUC on *Llama-2-7B* by an average of 30 percentage points. Notably, on *Mistral-7B*, ELCD reduces the FPR95 to 2.67% under IID conflicts and 16.59% under OOD conflicts, significantly mitigating the high false-positive rates that often hinder the real-world deployment of existing detectors in practical applications.

2 Related Work

2.1 Instruction Conflict and Defense Mechanisms

Large Language Models (LLMs) rely on instruction alignment to execute human intent, yet conflicts inevitably arise between system constraints and user instructions, particularly via prompt injection (Wallace et al., 2024; Liu et al., 2025a). Early defenses, such as keyword filtering or blacklists (Jain et al., 2023; Kumar et al., 2025), proved fragile against diverse and stealthy attacks (Shen et al., 2024; Wei et al., 2023a; Zou et al., 2023). Consequently, recent strategies have shifted toward input-side guardrails. These include lightweight discriminative models like Llama Guard (Inan et al., 2023; Zhang et al., 2024; Han et al., 2024; Lu et al., 2025) and methods that leverage the LLM’s

own reasoning for "self-auditing" prior to execution. However, these static defenses overlook risks that emerge during the autoregressive generation process in deployed systems. User intent can nudge the model into unsafe territory during generation, resulting in a phenomenon we term *Response Drift*. This transition from input compliance to output violation remains a critical gap in safety frameworks. In our work, we bridge this gap by introducing an energy-based framework that leverages internal hidden state perturbations to dynamically detect *Response Drift*, effectively capturing subtle violations that escape static guardrails.

2.2 Energy-Based Models

Energy-Based Models (EBMs) quantify the compatibility between data points and a predefined distribution using energy scores (Song and Kingma, 2021). While originally applied to density estimation (Hinton, 2002; Zhu et al., 1998), EBMs have become essential in anomaly detection by measuring the free energy gap to identify out-of-distribution (OOD) data (Liu et al., 2021; Grathwohl et al., 2020; Zhai et al., 2016; Wang et al., 2021). Recently, this framework has extended to monitoring LLM reliability, where factual errors or hallucinations are shown to trigger distinct energy fluctuations (Manakul et al., 2023; Ji et al., 2023; Azaria and Mitchell, 2023). Similarly, in safety alignment, research has mapped internal activations to an "energy landscape" to detect jail-break attempts (Zou et al., 2025). Building on these insights, our work analyzes energy perturbations within the deep hidden states of LLMs. This approach allows us to detect the subtle internal imbalances characteristic of *Response Drift*, providing a latent-state-based verification mechanism for completed responses.

3 Preliminary

3.1 Mathematical Foundations & Notation

We consider a large language model (LLM) $\mathcal{M}$ under a hierarchical instruction set containing a system-level instruction I_s and a user-level instruction I_u . The system instruction specifies behavioral constraints, such as formatting or linguistic restrictions, while I_u represents the user's task intent.

Ideally, the model generates a response R that satisfies I_u while strictly adhering to the constraints of I_s , formulated as $R \sim P_{\mathcal{M}}(\cdot | I_s, I_u)$. To quantify the alignment between the model's in-

ternal state and the prescribed hierarchy, we utilize Energy-Based Models. Specifically, for a discriminative head f_ϕ outputting logits from the internal representations, the free energy E is defined via the LogSumExp function:

$$E(\mathbf{x}; \phi) = -\log \sum_k \exp([f_\phi(\mathbf{v})]_k), \quad (1)$$

where $\mathbf{v}$ is the composite feature vector extracted from the final hidden layer by concatenating the final-token state h_T with the mean-pooled response segment $\text{Mean}(H_{\text{start}:T})$. Low energy corresponds to states aligned with I_s , while high energy indicates anomalous deviations.

3.2 Problem Formulation

Let $\mathcal{C}(\cdot)$ denote a semantic mapping that extracts constraints from an instruction. We use $R \models \mathcal{C}(I_s)$ to indicate that response R satisfies the system constraints, and $R \not\models \mathcal{C}(I_s)$ to indicate a violation.

We define two response states under the instruction hierarchy:

Definition 1 (Response States under Instruction Hierarchy). *Given an input sequence composed of I_s and I_u , and the generated response R , the behavioral state y is defined by the satisfaction of system constraints:*

1. Compliance (Normal, $y = 0$). *The model strictly adheres to system constraints. This state holds when the response satisfies the constraints of I_s , regardless of the user's intent:*

$$R \models \mathcal{C}(I_s) \quad (2)$$

2. Response Drift (Anomaly, $y = 1$). *The model yields to conflicting user instructions at the expense of system constraints. An instruction conflict occurs when I_u introduces constraints incompatible with or external to I_s (denoted as $\mathcal{C}(I_u) \setminus \mathcal{C}(I_s) \neq \emptyset$). Response drift is defined as the conjunction of such a conflict and a constraint violation:*

$$[\mathcal{C}(I_u) \setminus \mathcal{C}(I_s) \neq \emptyset] \wedge [R \not\models \mathcal{C}(I_s)] \quad (3)$$

The detection task is to identify the label y for a triplet (I_s, I_u, R) :

$$y = \begin{cases} 1, & \text{if } [\mathcal{C}(I_u) \setminus \mathcal{C}(I_s) \neq \emptyset] \wedge [R \not\models \mathcal{C}(I_s)], \\ 0, & \text{otherwise.} \end{cases} \quad (4)$$

Our goal is to learn a scoring function $S(I_s, I_u, R)$ from the model's internal energy signals.

3.3 Problem Visualization

To examine whether ELCD captures internal perturbations during *response drift*, we analyze the energy distribution of model states during training. The energy landscape reveals three observations:

- **Energy Basin Separation:** Compliant responses occupy a “low-energy basin,” with scores concentrated between -6 and -3 , indicating that adherent hidden states remain in a high-probability region of the instruction hierarchy.
- **Drift-Induced Energy Spike:** Response drift shifts the distribution toward higher values, centered between -2 and $+2$, showing that deviations from I_s push the model into a low-probability, high-energy state.
- **Spectral Gap for Detection:** A spectral gap appears between the two distributions, with a decision boundary near $E = -2.5$. This gap provides a quantitative signal for distinguishing compliance from drift even when surface text appears plausible.

These findings suggest that *Response Drift* is a latent shift rather than only a surface phenomenon, motivating the contrastive optimization framework introduced next for response-level drift detection.

4 Methodology

We propose ELCD, an energy-based response-level detector for identifying *Response Drift* from completed responses. As defined in Definition 1, drift corresponds to a latent deviation from system-level constraints after the model has already generated a plausible response. ELCD therefore verifies the response before delivery rather than only inspecting the input prompt. Instead of relying on surface patterns, it treats compliant behavior as a low-energy equilibrium and drift as a departure from this equilibrium. The framework consists of response-aware feature extraction, an energy projection head, and a margin-ranking objective that separates compliant and drifting responses in energy space. Figure 2 provides an overview.

4.1 Composite Feature Extraction

Detecting response drift requires features that reflect the generated response rather than the prompt alone. We extract representations from the final Transformer layer because these states contain the most abstract semantic information and the model’s

finalized generation intent. Let the full interaction sequence S concatenate the system instruction I_s , user instruction I_u , and response R , with hidden states $H = \{h_1, h_2, \dots, h_L\}$.

Response-Aware Masking. Since pooling over the full sequence can dilute response-specific drift signals with dominant prompt information, we use prefix matching to locate the assistant response start index t_{start} and extract features only from $H_R = \{h_{t_{\text{start}}}, \dots, h_L\}$. This isolates the latent trajectory produced during generation while keeping the conditioning context fixed.

Dual-View Representation. To capture both global semantic drift and local decision shifts, we concatenate the final-token state with the mean response representation:

$$\mathbf{v} = \text{Concat} \left(h_L, \frac{1}{L - t_{\text{start}} + 1} \sum_{t=t_{\text{start}}}^L h_t \right) \in \mathbb{R}^{2d}. \quad (5)$$

The two components are complementary. The final-token state h_L reflects the model’s terminal decision, which is useful when the response only drifts near the end of generation. The mean-pooled response state captures the overall semantic trajectory, making the representation more stable to token-level noise and local phrasing variation.

4.2 Energy Projection Architecture

The energy head f_ϕ maps $\mathbf{v}$ to a scalar energy score. We use a compact MLP with a progressive bottleneck $[2d \rightarrow 256 \rightarrow 128 \rightarrow 64 \rightarrow 2]$, which reduces the high-dimensional hidden representation while preserving non-linear separation between compliant and drifting states. We apply Dropout with rate 0.2 before the first linear layer and use ReLU activations between layers. Given the resulting two-dimensional logits, the free energy is computed via LogSumExp:

$$E(\mathbf{v}; \phi) = -\log \sum_k \exp([f_\phi(\mathbf{v})]_k). \quad (6)$$

This formulation follows the standard EBM view in which energy measures incompatibility with the learned constraint distribution. Lower energy indicates compatibility with system-level constraints, while higher energy indicates response drift.

4.3 Contrastive Optimization via Margin Ranking

We train the energy function with a contrastive objective that enlarges the gap between compliant

Figure 2: **Overview of the Energy-Driven Latent Conflict Detection (ELCD) framework.** ELCD extracts a composite response representation from mean-pooled hidden states (m) and the final-token state (h_T), then optimizes an energy landscape with pairwise margin ranking to separate compliant responses from response drift.

and drifting responses in the learned energy space. This is important because drifting responses may remain fluent and superficially task-relevant, making a purely local classification boundary unstable. The ranking objective directly shapes the energy landscape by pushing compliant samples toward a low-energy basin and drift samples toward a high-energy region for more reliable post-hoc detection.

Triplet Construction. We construct triplets (I_s, I_u, R) and label their features as compliant $\mathbf{v}_n$ or drifting $\mathbf{v}_d$. Within each batch, we sample pairs $(\mathbf{v}_n, \mathbf{v}_d)$ for ranking optimization, so the model learns relative energy ordering rather than only absolute labels.

Ranking Loss. We use a Pairwise Margin Ranking Loss to assign lower energy to compliant samples:

$$\mathcal{L}_{\text{rank}} = \mathbb{E}_{(\mathbf{v}_n, \mathbf{v}_d)} [\max(0, m + E(\mathbf{v}_n; \phi) - E(\mathbf{v}_d; \phi))] \quad (7)$$

Here, $m > 0$ is a margin hyperparameter (set to $m = 1.0$ in our main experiments), requiring drift samples to have energy at least m larger than compliant samples. When the gap is smaller than m , the loss penalizes the pair and pushes the two response states farther apart in the energy landscape.

4.4 Automated Label Construction

To provide scalable supervision, we use a rule-based verifier to extract operationalizable constraints $\mathcal{C}(I_s)$ and check the generated response R . The verifier covers format constraints, content restrictions, and structural requirements, including JSON-only output, mandatory keys, al-

lowed value ranges, forbidden words, language constraints, and length limits. If R violates any system constraint under a conflicting user instruction, we assign $y = 1$ (Drift); otherwise, $y = 0$ (Compliance). As described in Section 5.1, we additionally conduct manual audits. Importantly, the verifier is used only to construct training labels and is not available during inference. Thus, ELCD cannot inherit rule-based decisions at test time; it must learn latent response-level signals from hidden-state features and the trained energy head.

4.5 Post-hoc Response-Level Detection

During deployment, ELCD is applied after generation and before delivery. For each response, we run a forward pass over the full conversation, extract $\mathbf{v}$ from the response segment, and compute $E(\mathbf{v}; \phi)$ with the trained energy head. This makes the detector a post-hoc verification module rather than a decoding-time constraint, allowing it to catch violations that only become visible after the response is completed.

The detection decision is governed by a threshold τ :

$$\hat{y} = \begin{cases} 1 \text{ (Drift)} & \text{if } E(\mathbf{v}; \phi) > \tau, \\ 0 \text{ (Compliance)} & \text{if } E(\mathbf{v}; \phi) \leq \tau. \end{cases} \quad (8)$$

The threshold τ is calibrated on a held-out validation set, for example by maximizing F1 or targeting a high-recall operating point with a low false-positive rate. Since inference only adds a compact MLP head over hidden-state features, the additional

cost is modest compared with full LLM generation.

5 Experiments

In this section, we present the general experimental framework of our study, including the details of dataset construction (Section 5.1), the experimental setup (Section 5.2) and the experimental results (Section 5.3). We design a unified experimental pipeline to evaluate model behavior under instruction conflict settings across diverse benchmarks. Additional ablation and diagnostic analyzes are conducted to provide further insight into the experimental findings.

5.1 Dataset Construction

Data Sources and Structures. Following FocalLoRA (Shi et al., 2025), each instance is represented as a triplet (I_s, I_u, R) consisting of a system instruction, user instruction, and assistant response. Our conflict data are built from FocalLoRA-style programmatically verifiable constraints, including language, length, formatting, forbidden-word, and structured-output constraints. After response generation, we assign labels with the verifier and further conduct manual audits on randomly sampled labels. We also use IHEval (Zhang et al., 2025) for more complex conflict evaluation. Detailed in-domain conflict settings and representative task examples are provided in Section A.

Conflict Settings. We evaluate instruction conflicts under IID and OOD settings. IID examples are built from eight verifiable constraint fields, including case, digits, json, language, list, quote_presence, sentence_count, and word_length, covering formatting, language, length, quotation, digit, and structured-output conflicts. OOD examples are drawn from held-out IHEval fields, including lang_detect, translation, and verb_extract, which are excluded from training and differ in constraint type, task template, and text structure. Thus, OOD evaluation measures generalization to unseen constraint fields rather than template-level variation.

Data Splits. For the IID setting, we split the in-domain dataset into 70% training, 10% validation, and 20% held-out test sets using a stratified split over the binary conflict labels. The validation split is used for model selection and threshold calibration, while the held-out test split is used only for final in-domain evaluation. For the OOD setting, models are trained only on the training split of the in-domain dataset, and IHEval is kept as a disjoint

out-of-domain evaluation set. No IHEval examples are used for training.

Task Design. Building on the above constraint fields, we adapt the data format of the dataset to better align with the input conventions of large language models. The resulting task set spans multiple domains, including natural sciences, social sciences and history, technology and engineering, as well as creative and procedural tasks, enabling evaluation of response adherence across diverse dimensions. Representative conflict-task examples are shown in Table 5.

5.2 Experimental Setup

Models. We evaluate different methods on five open-sourced LLMs with model sizes ranging from 1.5 billion to 14 billion parameters: *Llama-2-7B-Chat* (Touvron et al., 2023), *Qwen2.5-1.5B-Instruct* (Yang et al., 2024), *Qwen2.5-14B-Instruct* (Yang et al., 2024), *Mistral-7B-Instruct-v0.2* (Jiang et al., 2023), and *Phi-3-Mini-128K-Instruct* (Abdin et al., 2024). For models that do not natively support separate system and user instruction templates, system and user instructions are concatenated into a single unified input prompt.

Baselines. We compare against five baselines, grouped by detection signal: input-side detectors, including Protect AI detector and Prompt-Guard; output-side behavioral detectors, including LLM-based detection and Known-answer detection; and the inner-side Attention Tracker. They are described as follows:

❶ **Trained Detectors.** These methods, represented by the Protect AI detector and Prompt-Guard (Protect AI, 2024; Meta Llama, 2025), are encoder-based prompt injection detectors fine-tuned to identify malicious instructions in user prompts. We instantiate them with *protectai/deberta-v3-base-prompt-injection-v2* and *meta-llama/Llama-Prompt-Guard-2-86M*, respectively.

❷ **LLM-based Detection.** This method treats prompt injection detection as a self-evaluation task performed by a standard language model (Phute et al., 2024; Jain et al., 2023). Following prior work, we query the model with a fixed safety prompt and use the computed conditional probability of the model responding “no” as a response-shift detection score.

❸ **Known-answer Detection.** The Known-answer detection evaluates prompt injection by testing whether a model can generate a specific predefined

Table 1: Detection performance under user–system instruction conflicts. We report PR-AUC (denoted as AUC) and FPR at 95% TPR (FPR95) in IID and OOD evaluation settings. Higher PR-AUC and lower FPR95 indicate better performance. The best results are highlighted in bold, and the second-best results are underlined.

target output under a fixed anchor instruction, and a resulting lower target probability indicates stronger response deviation(Liu et al., 2025b).

④ **Attention tracker.** Attention Tracker detects response deviation by measuring how much a language model’s attention remains focused on the instruction tokens during generation(Hung et al., 2025). The response deviation detection score of each input is defined as one minus the instruction-attention across the identified attention heads.

Baseline Coverage. Together, these baselines cover complementary detection signals: prompt-only inspection, output-side model judgment, target-answer consistency, and generation-time attention tracking. This allows us to evaluate whether response drift is better captured from surface prompts, behavioral outputs, or internal model dynamics. Since our setting focuses on completed responses under instruction hierarchy conflicts, this comparison directly tests the value of latent response-level verification. More detailed principles are provided in Section B.

Evaluation Protocols and Metrics. We assess robustness under two settings: *In-Distribution (IID)* and *Out-of-Distribution (OOD)*. In the IID setting, the in-domain data are split into 70%/10%/20% train/validation/test partitions, with conflict types shared across splits. In the OOD setting, models are trained on the in-domain training split and evaluated on held-out conflict types from IHEval. Performance is quantified using **Precision-Recall**

Area Under the Curve (PR-AUC), a threshold-independent metric suitable for imbalanced safety benchmarks, and the **False Positive Rate at 95% True Positive Rate (FPR95)**. FPR95 measures practical usability by quantifying false alarms when capturing 95% of violations; a lower value ensures high safety coverage with minimal disruption to valid user interactions (Hendrycks and Gimpel, 2018; Davis and Goadrich, 2006).

5.3 Experimental Results

Main Results under Instruction Conflicts. Table 1 summarizes the detection performance of ELCD and baseline detectors across five open-source LLM backbones. ELCD outperforms all baselines on both PR-AUC and FPR95, showing robust detection across architectures and model scales. Under the IID user–system conflict setting, ELCD improves PR-AUC by 30 percentage points on *Llama-2-7B*. More importantly, it exhibits a pronounced advantage in FPR95; on *Mistral-7B*, the second-best result is 90.54%, whereas ELCD reduces FPR95 to 2.67%, implying far fewer false positives in high-recall regimes.

These results highlight the limitation of existing detectors in handling structural deviations induced by hierarchical conflicts. While some baselines attain high PR-AUC scores (e.g., 89.33% on Phi3), their FPR95 remains prohibitively high, often approaching 100%. The gains also do not scale strictly with model size, suggesting that ELCD captures signals that generalize across architectures.

Margin	Llama2-7B		Qwen2.5-1.5B	
	AUC	FPR95	AUC	FPR95

✓	✓	99.67	15.70	99.27	6.45

Table 3: **Ablation on key components.** Analysis of Mean Pooling and Last Token strategies.

Results under OOD Conflict Settings. Table 1 reports performance under OOD user–system conflicts, where conflict patterns are unseen during training. This setting is more difficult and closer to practical distribution shifts. Overall, baseline methods exhibit clear degradation; for example, the LLM-based method on *Mistral-7B* drops from 59.95% to 49.76% PR-AUC. In contrast, ELCD maintains stable performance across backbones. On *Mistral-7B*, Prompt-Guard and Known-answer incur FPR95 values of 74.12% and 90.27%, respectively, whereas ELCD reduces FPR95 to 16.59%, an absolute reduction of 57.53 percentage points compared to Prompt-Guard.

These results demonstrate that ELCD generalizes to unseen conflict scenarios by capturing intrinsic latent signals rather than relying only on superficial prompt features.

Interpretation. The OOD results suggest that response drift is not merely a template-matching artifact. Although the held-out conflicts differ in constraint type and task form, drifting responses still induce separable hidden-state patterns after generation. This helps explain why input-side detectors degrade under distribution shift: they mainly inspect whether the prompt resembles known attack patterns, while ELCD evaluates whether the completed response remains compatible with the system-level constraint.

Diagnostic Analysis. To investigate the impact of key architectural decisions and hyperparameters, we conduct ablation studies on the margin parameter of the energy-based objective and the feature representation strategies. Table 2 and Table 3 summarize these results.

We analyze the sensitivity of our method to the margin, which enforces separation between posi-

tive and negative energy scores. As shown in Table 2, performance does not improve monotonically with a larger margin. Setting the margin to 1.0 yields the best trade-off across *Llama2-7B* and *Qwen2.5-1.5B*. Increasing it to 1.5 raises FPR95; on *Llama2-7B*, FPR95 deteriorates from 15.70% to 25.70%. Conversely, a smaller margin (0.5) provides insufficient separation, resulting in sub-optimal detection. This suggests that a moderate margin is important: it creates an energy gap without over-penalizing borderline responses whose latent states remain close to the compliant manifold.

Table 3 isolates the contributions of global semantics (Mean Pooling) and local generative signals (Last Token). The results demonstrate that neither feature set is sufficient on its own. Using only the last token or mean pooling results in significantly higher false positive rates. On *Qwen2.5-1.5B*, for instance, employing single-feature representations yields FPR95 values between 27.21% and 34.36%. However, concatenating these features reduces the FPR95 to 6.45%. This substantial improvement indicates that global sentence-level semantics and local token-level probabilities capture complementary information, which is essential for robustly distinguishing between safe and conflicted instructions. Intuitively, the last token reflects the model’s terminal instruction-following decision, while mean pooling captures the response-level semantic trajectory; combining them stabilizes detection when drift appears gradually or only near the end of generation.

6 Conclusion

In this work, we define *Response Drift*, where LLMs deviate from system constraints due to conflicting user instructions. Static defenses often fail to capture these violations or incur high false-positive rates. To address this, we introduce ELCD, an energy-based framework that detects drift by analyzing internal latent dynamics via a composite representation of instantaneous intent and semantic trajectory. Evaluations across five LLM backbones demonstrate strong accuracy and generalization. ELCD reduces false-positive rates to practical levels, highlighting the value of internal state monitoring for reliable AI systems. These findings suggest that post-generation verification can complement prompt-side defenses in deployment. Future work may extend this framework to broader semantic policies and multi-turn interactions.

Limitations

ELCD requires access to hidden states of the target language model, which limits its direct applicability to closed-source API-only systems. Our experiments focus on open-weight instruction-following models and programmatically verifiable instruction conflicts, such as formatting, language, length, and structural constraints. Although these settings enable scalable and reliable labeling, they may not fully cover complex semantic policies, subjective safety requirements, or multi-turn interactions. In addition, the detector is trained and calibrated on specific model backbones, and its performance may require recalibration when deployed with substantially different models, decoding settings, or task distributions.

Ethical Considerations

This work aims to improve the detection of instruction hierarchy violations and reduce non-compliant model outputs before delivery. ELCD is designed as a complementary post-generation verification module and can be integrated with prompt-side defenses, policy checkers, or human review in high-risk deployment settings. Like other learned detectors, ELCD may produce false positives that unnecessarily flag benign responses or false negatives that miss constraint violations. Therefore, deployment thresholds should be calibrated according to the risk level of the application. Our experiments use synthetic or benchmark-style instruction conflicts and do not require collecting private user data.

A Dataset Details

A.1 Types of Constraints

We construct the in-domain dataset from eight programmatically verifiable constraint families. Each instance contains five fields: `id`, `system_message`, `user_message`, `task`, and `label`. For each constraint family, the dataset includes both a direct setting and a permutation setting, where the system-side and user-side constraints are swapped. Each setting contains 200 instances, balanced into 100 normal and 100 conflict examples. Table 4 summarizes the actual constraint pairs used in the in-domain dataset.

A.2 Base Tasks List

The base task pool covers general knowledge, science, history, technology, procedural writing, literature, safety advice, and creative writing. We list fifteen representative in-domain tasks in Table 5; conflict rows pair a system instruction with a user instruction, while normal rows leave `user_message` empty.

Example: Output Format Conflict. The following example corresponds to an output-format conflict instance. The system instruction requires a strict JSON response, while the user instruction asks for plain prose without JSON formatting.

System instruction:

Respond in JSON format with keys 'answer' and 'reasoning', no additional text.

User instruction:

Respond in plain text prose, no JSON formatting.

Task:

Describe the process of photosynthesis.

This instance is labeled as `conflict` because following the user instruction would violate the system-level output-format constraint. In our response-level setting, a generated answer is labeled as response drift only when the final response fails to satisfy the governing system constraint.

B Baseline Detection Principles

We summarize the compared baselines by the type of signal they use for detecting instruction conflicts. This section is intended to clarify their operating principles, while the formal complexity discussion is reserved for ELCD in Section C.

Input-side Detectors. Protect AI detector and Prompt-Guard inspect the user prompt before generation. They aim to recognize malicious or conflicting instructions from input text alone. This makes them easy to deploy as front-end filters, but they cannot observe whether the final response actually follows or violates the system-level instruction.

LLM-based Detection. LLM-based detection formulates safety checking as a self-evaluation or judge-style task. The original interaction and generated response are provided to a language model, which then estimates whether a violation has occurred. This approach can inspect the output, but it depends on an additional model judgment and may inherit the judge model’s calibration and reasoning errors.

Known-Answer Detection. This method checks whether the model remains anchored to a predefined target answer under a fixed instruction. A lower probability assigned to the expected answer is treated as evidence of response deviation. It is useful when an anchor answer is available, but less flexible for open-ended tasks whose correct response is not known in advance.

Attention Tracker. Attention Tracker monitors how generated tokens attend to instruction tokens during decoding. It interprets reduced attention to the governing instruction as a sign of response deviation. This provides an internal generation-time signal, but it requires access to attention patterns and depends on identifying which heads or layers should be monitored.

C Complexity Analysis

The purpose of this analysis is to clarify the additional inference overhead introduced by ELCD. Since ELCD is designed as a post-generation verification module, its practical cost should be understood as the extra computation added after the target LLM has produced a response. We therefore focus the formal complexity derivation on ELCD.

ELCD detects response drift by extracting hidden states from the completed conversation and applying a lightweight MLP energy head. Let T_p denote the prompt length, T_r the generated response length, $T = T_p + T_r$ the full conversation length, and d the hidden dimension of the target LLM. After the response segment is located, the detector-side computation consists of mean pooling over response hidden states and projecting the resulting

Conflict Type	Direct Setting: System Constraint $\rightarrow$ User Constraint	Permutation Setting: System Constraint $\rightarrow$ User Constraint
Language	English only $\rightarrow$ French only	French only $\rightarrow$ English only
Digit Presence	No digits (0-9) $\rightarrow$ include at least three digits	Include at least three digits $\rightarrow$ no digits (0-9)
Output Format	JSON with keys 'answer' and 'reasoning', no additional text $\rightarrow$ plain-text prose with no JSON formatting	Plain-text prose with no JSON formatting $\rightarrow$ JSON with keys 'answer' and 'reasoning', no additional text
List Structure	Exactly five numbered items, starting with '1.', '2.', etc. $\rightarrow$ a single paragraph with no list formatting or line breaks	A single paragraph with no list formatting or line breaks $\rightarrow$ exactly five numbered items, starting with '1.', '2.', etc.
Quotation Marks	Include at least one phrase wrapped in double quotes $\rightarrow$ do not use quotation marks	Do not use quotation marks $\rightarrow$ include at least one phrase wrapped in double quotes
Sentence Count	Exactly 10 sentences $\rightarrow$ at least five sentences	At least five sentences $\rightarrow$ exactly 10 sentences
Word Count	At least 300 words $\rightarrow$ less than 50 words	Less than 50 words $\rightarrow$ at least 300 words
Case	English in all capital letters $\rightarrow$ English in all lowercase letters	English in all lowercase letters $\rightarrow$ English in all capital letters

Table 4: **Conflicting constraint pairs** instantiated in the in-domain dataset. The direct and permutation settings use opposite system/user constraint directions.

composite feature through the energy head:

$$O(T_r d) + O(d \cdot 256 + 256 \cdot 128 + 128 \cdot 64 + 64 \cdot 2). \quad (9)$$

Because the MLP widths are fixed constants, the detector-side overhead simplifies to:

$$O(T_r d). \quad (10)$$

This term corresponds to response-segment pooling plus a small feed-forward projection. In self-hosted deployments where hidden states are already exposed during generation, this is the only additional computation required by ELCD. If the serving stack does not expose hidden states, a separate verification forward pass over the completed conversation may be used. In that case, the total verification cost becomes:

$$C_{\mathcal{M}}(T) + O(T_r d), \quad (11)$$

where $C_{\mathcal{M}}(T)$ denotes one forward pass through the target LLM. Even in this conservative setting, ELCD avoids additional autoregressive generation, external judge calls, or task-specific target-answer scoring. Thus, the extra cost introduced by the detector remains acceptable for open-weight or self-hosted systems that can access hidden states.

Overall, ELCD provides a lightweight response-level verification mechanism. It observes the completed response like output-side detectors, while its learned scoring component only adds response pooling and a compact MLP once hidden states are available. This supports the practical claim that ELCD improves drift detection without imposing prohibitive inference overhead.

D Deployment Details

D.1 Hardware & Training Configuration

The experiments are conducted using NVIDIA GeForce RTX 3090 GPUs as the hardware platform, coupled with an Intel(R) Xeon(R) Gold 6240 CPU @ 2.60GHz. The deep learning framework employed is PyTorch, version 2.0.1, alongside CUDA version 11.7. Unlike fine-tuning-based alignment methods, ELCD does not update the target LLM parameters. The target model is used as a frozen feature extractor, and only the lightweight energy head is trained.

Backbone Usage. We evaluate ELCD on five open-weight instruction-following backbones, covering Llama-2-7B-Chat, Mistral-7B-Instruct-v0.2, Phi-3-Mini-128K-Instruct, and Qwen2.5-Instruct at both 1.5B and 14B scales. During feature extraction and deployment, the backbone is run with hidden-state outputs enabled; no gradient is propagated into the backbone.

Feature Construction. For each completed interaction, we concatenate the system instruction, user instruction, and generated response using the model-specific chat template. We identify the start of the assistant response by comparing the tokenized prompt prefix with the tokenized full conversation. From the last Transformer layer, we extract the final-token hidden state and the mean-pooled hidden state over the response segment. These two vectors are concatenated to form the detector input.

Energy Head Configuration. The detector is a

Instance ID	Constraint Type	Label	Task Prompt

Table 5: **Representative instances** from the in-domain dataset.

compact MLP with architecture $2d \rightarrow 256 \rightarrow 128 \rightarrow 64 \rightarrow 2$, where d is the hidden size of the target LLM. We apply dropout with rate 0.2 before the first linear layer and use ReLU activations between hidden layers. The energy score is computed as $E(\mathbf{v}) = -\log \sum_k \exp(f_\phi(\mathbf{v})_k)$, where larger energy indicates a higher likelihood of response drift.

Training Objective. We train the energy head for 20 epochs with Adam, learning rate 1×10^{-4} , batch size 64, and random seed 42. Training uses a stratified 70/10/20 split for train, validation, and held-out test data. Within each mini-batch, compliant and drifting examples are randomly paired, and the head is optimized with the pairwise margin ranking loss described in Section 4.3. We select the checkpoint with the best validation pairwise energy accuracy.

Threshold Calibration. After training, we compute energy scores on the validation set and select a decision threshold τ . Unless otherwise specified, τ is chosen by maximizing validation F1; we also support high-recall calibration and normal-score quantile calibration. The selected threshold is then fixed for held-out test and OOD evaluation.

D.2 Details of Implementing ELCD

Here we present a minimal deployment procedure for ELCD. The detector is placed after response generation and before response delivery. It therefore acts as a post-hoc verification module: the application first lets the target LLM produce a complete answer, then ELCD scores the completed conversation and blocks or flags the response when the energy exceeds the calibrated threshold.

Deployment Procedure. Given a frozen LLM $\mathcal{M}$, tokenizer, trained energy head f_ϕ , threshold τ , system instruction I_s , and user instruction I_u , deployment proceeds as follows:

1. Generate the candidate response R from $\mathcal{M}(I_s, I_u)$.
2. Build the prompt-only prefix P and full conversation S with the model template.
3. Locate the response start by longest-prefix matching between tokenized P and S .
4. Forward S with hidden-state outputs enabled and extract the response states H_R .
5. Compute the composite response feature and its energy score.
6. Flag the response if $E(\mathbf{v}) > \tau$; otherwise, deliver it to the user.

Response-Segment Localization. Different model families use different chat templates, so relying on

a fixed special token is brittle. We instead locate the response boundary through prefix matching: the tokenized prompt-only prefix is compared against the tokenized full conversation, and the first mismatch marks the start of the assistant response. This procedure is compatible with Llama-style, Mistral-style, ChatML-style, and Phi/Qwen templates.

Deployment Modes. In self-hosted systems, hidden states can be collected during the same forward pass used for generation or through a lightweight verification forward pass after generation. The former minimizes latency when hidden states are already exposed by the serving stack; the latter is easier to integrate into existing deployments because it treats ELCD as an external verification module. In both cases, the learned detector itself only adds response pooling and a small MLP computation.

Fallback Handling. ELCD outputs a scalar energy score rather than directly rewriting the response. In deployment, a flagged response can be rejected, regenerated with stronger system reminders, routed to a stronger verifier, or sent for human review depending on the application’s safety requirement. This separation keeps the detector modular and avoids coupling the method to a particular decoding or refusal policy.
